plates, corresponding to 19,000 psi working stress with safety factor 5. Allowable crushing stresses in structural joints are 40,000 psi for rivets in double shear, 32,000 psi for rivets in single shear. With aluminum alloys the crushing or bearing strengths are dependent on the plate or shape material, and its heat treatment. Values range from 34,000 psi ultimate in soft material to 129,000 psi ultimate in hard material (see *Alcoa Structural Handbook*).

Tearing Strength. A joint may fail by tearing of the plate between the rivet holes. Resistance to tearing at any section is equal to the net area remaining after the holes have been made times the tensile strength of the plate, S_t. ASME code value for S_t is 55,000 psi ultimate, or 11,000 psi allowable with factor of safety 5. For structural steel the allowable is 20,000 psi.

Joint Analysis. Actual strength of a riveted joint is found by applying the foregoing principles. Total load required to cause failure in each mode is calculated. Lowest of these values, expressed as a percentage of the load to cause failure of the solid plate, is called the efficiency.

Double and triple riveted joints may fail by a combination of shearing, crushing, and tearing. Tables 5 to 10 show the dimensions and efficiencies of standard boiler joints, as published in the *Boiler Book* of the Hartford Steam Boiler Inspection and Insurance Company. The dimensions D, E, and F in these tables may be increased for convenience in riveting, without affecting the efficiency of the joint. They should not be decreased.

Notation. a = diameter of rivet hole, usually $^1/_{16}$ in. greater than rivet, t = thickness of plate, t_c = thickness of cover plates, p = pitch of inner row of rivets, P = pitch of outer row of rivets, all in inches; and let s_s = shearing strength of rivets; s_t = tensile strength of plate, s_c = crushing strength of rivet or plate, all in pounds per square inch. Then the resistance for the various joints are as follows.

Single-riveted Lap Joint (Fig. 6). Resistance to shearing one rivet = $(^1/_4\pi d^2)s_s$.

Resistance to tearing plate between rivets = $(P - d)ts_t$.
Resistance to crushing of rivet or plate = dts_c.

Double-riveted Lap Joint (Fig. 7). Resistance to shearing two rivets = $2(^1/_4\pi d^2)s_s$.

Resistance to tearing between two rivets = $(P - d)ts_t$.
Resistance to crushing in front of two rivets = $2dts_c$.
Strength of solid plate = Pts_t.

Single-riveted Lap Joint, Inside Cover Plate (Fig. 8). Resistance to tearing between outer row of rivets = $(P - d)ts_t$.

Resistance to tearing between inner row of rivets, and shearing outer row of rivets $= (P - 2d)ts_t + (^1/_4\pi d^2)s_s$.
Resistance to shearing three rivets = $3(^1/_4\pi d^2)s_s$.
Resistance to crushing in front of three rivets = $3tds_c$.
Resistance to tearing at inner row of rivets and crushing in front of one rivet in outer row $= (P - 2d)ts_t + tds_c$.
Strength of solid plate = Pts_t.

Double-riveted Lap Joint with Inside Cover Plate (Fig. 9). Resistance to tearing at outer row of rivets = $(P - d)ts_t$.

Resistance to shearing four rivets = $4(^1/_4\pi d^2)s_s$.
Resistance to tearing at inner row and shearing outer row of rivets $= (P - 1\,^1/_2d)ts_t + (^1/_4\pi d^2)s_s$.
Resistance to crushing in front of four rivets = $4tds_c$.
Resistance to tearing at inner row of rivets, and crushing in front of one rivet $= (P - 1\,^1/_2d)ts_t + tds_c$.
Strength of solid plate = Pts_t.

Double-riveted Butt Joint (Fig. 10). Resistance to tearing at outer row of rivets = $(P - d)ts_t$.

Resistance to shearing two rivets in double shear and one in single shear = $5(^1/_4\pi d^2)s_s$.

Resistance to tearing at inner row of rivets and shearing one of the outer row of rivets = $(P - 2d)ts_t + (^1/_4\pi d^2)s_s$.

Resistance to crushing in front of three rivets = $3tds_c$.

Crushing in front of two rivets and shearing one rivet = $2tds_c + (^1/_4\pi d^2)s_s$.

Strength of solid plate = Pts_t.

Triple-riveted Butt Joint (Fig. 11). Resistance to tearing at outer row of rivets = $(P - d)ts_t$.

Resistance to shearing four rivets in double shear and one in single shear = $9(^1/_4\pi d^2)s_s$.

Resistance to tearing at middle row of rivets and shearing one rivet = $(P - 2d)ts_t + (^1/_4\pi d^2)s_s$.

Resistance to crushing in front of four rivets and shearing one rivet = $4dts_c + (^1/_4\pi d^2)s_s$.

Resistance to crushing in front of five rivets = $5dts_c$.

Strength of solid plate = Pts_t.

Quadruple-riveted Butt Joint with Two Cover Plates (Fig. 12). Resistance to tearing at outer row of rivets = $(P - d)ts_t$.

Resistance to tearing at the third row and shearing one rivet in the outer row = $(P - 2d)ts_t + (^1/_4\pi d^2)s_s$.

Resistance to tearing at the second row of rivets and shearing three rivets = $(P - 4d)ts_t + 3(^1/_4\pi d^2)s_s$.

Resistance to double-shearing eight rivets and single-shearing three rivets = $19(^1/_4\pi d^2)s_s$.

Resistance to crushing in front of eight rivets and single-shearing three rivets = $8dts_c + 3(^1/_4\pi d^2)s_s$.

Resistance to crushing in front of eleven rivets = $11dts_c$.

Resistance to tearing at the third row of rivets and crushing in front of one rivet in the outer row = $(P - 2d)ts_t + dts_c$.

Resistance to tearing at the second row of rivets and crushing in front of three rivets = $(P - 4d)ts_t + 3dts_c$.

Strength of the solid plate = Pts_t.

Lap-riveted Girth Joints. (*Boiler Book* of Hartford Steam Boiler Inspection & Insurance Co.). In horizontal tubular boilers, tanks, and similar vessels, it is customary to use rivets of the same size in both girth and longitudinal seams. If the heads are not stayed by tubes or through braces, the strength of the girth joints should be at least 50% of that required for the longitudinal joints. The joints in Table 9 are designed to meet these requirements; a higher efficiency could be obtained in some cases by using a rivet of different size. It is assumed in each case that the efficiency of the corresponding longitudinal joint is not greater than that of the standard design of quadruple-riveted butt joints given in Table 8.

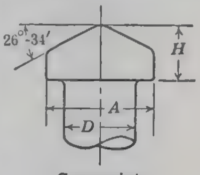
Where 50% or more of the load which would act on an unstayed head of the same diameter as the shell is relieved by the effect of tubes or through stays, as in tubular boilers, the strength of the girth joints should be at least 35% of that required in longitudinal joints. When the girth joints are exposed to products of combustion, the shearing strength of the rivets should be not less than 50% of the full strength of the plate corresponding to the thickness at the joint. Table 10 is designed for such conditions, rivets of the same size as standard butt joints being used. Plates thicker than $^9/_{16}$ in. are not advised if the girth seams are exposed to fire or products of combustion. In those portions of the seams exposed to fire, the riveting should be started at the bottom of the boiler and carried up continuously on both sides, reaming the holes anew as the riveting is carried up to the full diameter of the boiler.

Precautions to Be Observed in Making Riveted Joints. Plates must be brought into close contact before the rivet is driven, either by bolts close to the rivet hole, firmly drawn up, or by a power-actuated holding device. The latter sometimes is incorporated in power-driven riveting machines.

Rivet holes must be perfectly aligned in the members that are to be joined. This is best insured by drilling of the members. Punched holes, usually used in structural work, are difficult of alignment, and have a stress set up around the hole which seriously impairs the strength of the plate unless it is subsequently relieved by reaming, drilling, or annealing. Punched plates or structural members in which the holes do not align never should be brought into alignment by drifting with taper pins. This practice usually causes serious injury to the plates or structural members. The best practice with punched members is to punch the holes smaller than required, and, after assembly, ream or drill them to the correct size.

The rivet must completely fill the hole, and consequently must be upset throughout its entire length. Otherwise, an undue concentrated stress, either in bearing or in shearing, may be brought upon adjoining rivets. To insure complete upsetting, all the larger sizes of rivets should be power driven. Care must be taken in machine riveting to avoid applying a riveting pressure that will set up stresses in the plate tending to crush it. It is essential in machine riveting that the pressure be so applied that the heads are concentric. Pressure should be maintained on the rivet until it has cooled sufficiently to hold the plate firmly.

Aluminum Rivets. Squeeze-type riveters should be used on aluminum rivets where possible. Pneumatic hammers and back-up tools should be heavier than for steel rivets of the same size. The flat-cone-type driven head shown in Fig. 13 facilitates driving and has a good appearance.



Cone point

$A = 1.50D$
$H = 0.75D$

Fig. 13. Preferred form of driven head for aluminum rivets.

Cold driving is used for 53S-T61 and A17S-T alloy rivets as received from the manufacturer. The flat-cone head (Fig. 13) is readily driven with a pneumatic hammer in sizes up to $^5/_8$ in. in diameter. Larger rivets should be squeeze driven. Cold driving is also used for 17S and 24S alloy rivets where proper heat-treating equipment is available. Such rivets should be heat treated, quenched, and driven immediately to take advantage of the workability of the metal before age hardening occurs. This "as quenched" workability can be retained for 8 to 10 hr by refrigerating at 32 F or less and storing at this temperature until use. Such cold driving normally is restricted to sizes less than $^1/_2$ in. diameter.

Hot driving is often desirable for rivets over $^1/_2$ in. in diameter because the driving pressures are only one-third to one-fifth as great as for corresponding cold rivets. For hot driving, 53S rivets should be brought to 1030 to 1050 F in a furnace having accurate temperature control. Rivets must be transferred to the work as quickly as possible and driven at once, quenching being obtained by contact with cold metal and tools. Rivets of 17S alloy can be hot driven, procedure being similar, but with a heating range of 930 to 950 F.

FORM OF RIVETED JOINTS FOR MORE THAN TWO PLATES. In tanks, boilers, and all pressure vessels requiring tight seams, the problem often is to join three or four plates. Figure 14 shows method of making such joints.

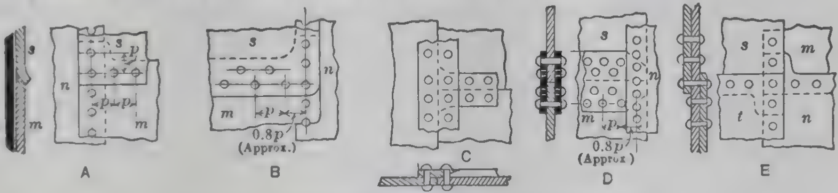


Fig. 14. Riveted joints for more than two plates.

Figure 14*A* is a junction of three plates, *m*, *n*, and *s*, where both seams are single-riveted lap joints. The corner of *m* is drawn to an edge and tucked under *s*.

Figure 14*B* is a junction of three plates; one seam is single riveted and the other is a double-riveted lap joint. As before, the corner of *m* is drawn down and tucked under *s*.

Figure 14*C* is a junction of three plates with butt straps; the longitudinal butt strap is planed down and tucked under the cross butt strap.

Figure 14*D* is the junction of three plates; the cross seam is a single-riveted lap joint, and the longitudinal joint is a double-riveted butt joint with double cover plates. The upper cover plate is planed on the end so that it can be tightly calked where it abuts against plate *n*.

Figure 14*E* is a method of joining four plates; both seams are single-riveted lap joints, *n* and *s*, both being drawn down as shown.

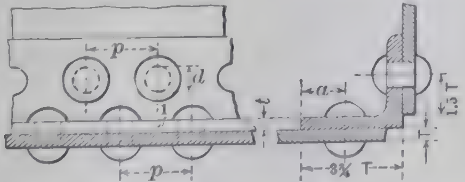

Fig. 15. Use of angle to join plates at right angles.

Junction of plates not in the same plane usually is effected by means of a rolled structural form. Figure 15 shows an angle used with plates at right angles to each other. If

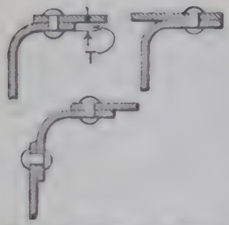

FIG. 16. Use of flanged plates for joining plates in different planes.

T = thickness of plate and t = mean thickness of angle leg, then $t = T + 1/16$ in. The width w of each leg of the angle $= 3.75T$; the diameter d of the rivet $= 2T$ and $a = 1/2(w - t)$, where w = width of angle.

Figure 16 shows methods of connecting plates by flanging the plates themselves instead of using angles. Care should be taken not to use too sharp a radius of curvature, and the flange should be annealed after it is bent. The inside radius of the flange must be greater than the thickness of the plate even with the mildest steel. Unwin recommends an inside radius of at least $4T$.

FASTENERS FOR WOOD JOINTS

8. NAILS AND SCREWS

NAILS. Table 1 lists the sizes, lengths, and numbers to the pound of the commoner standard steel wire nails. Decimal sizes are listed in Table 2.

Holding Power of Nails. Withdrawal resistance tests at the U. S. Forest Products Laboratory indicate that holding power of wire nails and spikes depends on density of the wood, diameter of the nail, and depth of penetration. By applying a factor of safety of 6, the safe load may be expressed as

$$P = 1150G^{5/2}D \tag{1}$$

where P is the safe load per lineal inch of penetration into the side grain of seasoned wood, pounds; G is the specific gravity of the wood; and D is the diameter of the nail, inches. Table 3 lists values of specific gravity, and also $G^{5/2}$, for various wood species. Tables 1 and 2 list values of D for various standard wire nail sizes.

* Based on oven-dry weight and volume.

Nails driven parallel to the grain show a withdrawal resistance only 75% or even 50% of that for nails driven into the side grain. Nails driven into green wood have higher resistance while the wood is green, but will lose a large part of their holding power as the wood seasons. Some wood species indicate lower or higher resistance than shown by eq. 1, and coatings may affect holding power either favorably or adversely. See Ref. 1 for further data. In general, a long sharp point gives higher holding power than a common diamond point, particularly with softer woods. However, if the wood tends to split, this tendency will be increased by the sharp point.

Lateral Resistance of Nails and Wire Spikes. For nails driven at right angles to the grain, safe lateral resistance may be expressed by the equation

$$P = K_1 D^{3/2} \tag{2}$$

where P is the safe lateral load per nail, pounds; D is the nail diameter, inches; and K_1 is a constant which depends on the wood species (see Table 3). Equation 2 is based on a depth of penetration, into the block receiving the point, of not less than ten times (for dense woods) to fourteen times (for soft woods) the nail diameter. If the nails are holding metal to wood, the safe lateral load can be increased about 25%. When nails are driven parallel to the grain, the loads should be reduced to 60% of the values given by eq. 2.

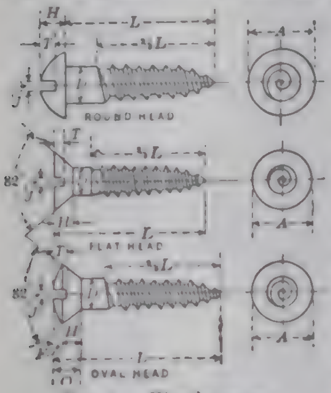

Fig. 1. Wood screws.

Resistance of Drift Bolts. Resistance to withdrawal of round drift bolts driven perpendicular to the grain into holes having 1/8 in. less diameter than the bolt is

$$P = 6000G^2D \tag{3}$$

where P is the maximum withdrawal load per lineal inch of penetration, pounds; G is the specific gravity of the wood species (see Table 3 for G and G^2); and D is the drift bolt diameter, inches.

WOOD SCREWS are standardized in three styles shown in Fig. 1, with either style of cross recess (Fig. 16, p. 10-40) available as alternatives to the screwdriver slot. Dimensions are given in Table 4.

Withdrawal Resistance of Wood Screws. Safe load for a common wood screw inserted into the side grain of seasoned wood is

$$P = 1700G^2D \tag{4}$$

where P is the safe load (assuming safety factor 6), pounds; G is the specific gravity of the wood (see Table 3 for G and G^2); and D is the diameter of the screw (see Table 4). Equation 4 may be considered accurate to within plus or minus 10 to 15%, and is based on depth of penetration, into the block receiving the point, not less than two-thirds the length of the screw, the screws being inserted into holes having diameter about 70% (for softwoods) to 90% (for hardwoods) of the root diameter of the screw. If the screws are driven parallel to the grain and no splitting occurs, the safe loads are about 75% of those given by eq. 4. Equation values are applicable to the following screw lengths and gages:

Screw length, in.	1/2	3/4	1	1 1/2	2	2 1/2	3
Gage limits	1–6	2–11	3–12	5–14	7–16	9–18	12–20

For lengths and gages outside these limits, safe loads are likely to be less, especially in denser woods where screw failures rather than wood failures may occur.

Lateral Resistance of Wood Screws. Safe lateral load for a wood screw may be expressed by an equation of the form

$$P = K_2D^2 \tag{5}$$

where P is the safe lateral load per screw, pounds; D is the diameter of the shank (see Table 4), pounds; and K_2 is a constant which depends on the wood species (see Table 3). Equation 5 is based on a depth of penetration, into the block receiving the point, not less than seven times the screw diameter. If the screws are holding metal to wood, the safe lateral resistance may be increased 25% above the values given by eq. 5.

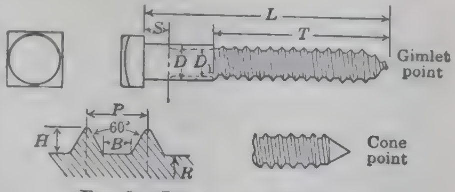

FIG. 2. Lag bolt. See Table 5.

LAG BOLTS are made with a cone point or a gimlet point, and a square head (Fig. 2). Leading dimensions are listed in Table 5.

Table 5. Dimensions of Lag Bolts

(Industrial Fasteners Institute. See Fig. 2. All dimensions in inches.)

Diameter of Bolt, D	Threads per Inch	Thread Dimensions: Pitch, P	Flat at Root, B	Depth of Thread, H	Root Diameter, R	Length of Shoulder for Rolled Thread, S: To 1 1/2 Long	1 5/8 1 3/4 Long	2 and Longer

3/8	7	.143	.062	.055	0.265	1/8	1/4	1/4
7/16	7	.143	.062	.055	0.328	5/32	1/4	5/16
1/2	6	.167	.072	.064	0.371	5/32	1/4	5/16
9/16	6	.167	.072	.064	0.435		5/16	3/8
5/8	5	.200	.086	.077	0.471		5/16	3/8
3/4	4 1/2	.222	.096	.085	0.579		3/8	1/2
7/8	4	.250	.108	.096	0.683		3/8	1/2
1	3 1/2	.286	.123	.110	0.780			5/8
1 1/8	3 1/4	.308	.133	.119	0.887			5/8
1 1/4	3 1/4	.308	.133	.119	1.012			5/8

Threads shall be rolled or cut. Diameter of rolled thread shank is not dimensioned, but is indicated by D_1 in Fig. 2. All rolled-thread lag bolts shall be provided with shoulder, S.

For minimum thread lengths, see below.

Dimensions of heads are the same as those for regular, unfinished, square-head machine bolts (see p. 10-33, Table 24).

Bolt length, L	1	1 1/2	2	2 1/2	3	4	5	6	7	8	9	10
Thread length, T	3/4	1 1/8	1 1/2	1 3/4 *	2	2 1/2	3	3 1/2	4	4 1/2	5	5 1/4

* For No. 10 and 1/4-in. sizes, T = 1 1/2; for 5/16 and 3/8-in. sizes, T = 1 5/8.

For bolt lengths greater than 10 in., thread is about one-half the length of the bolt.

Lag Bolt Joint Assembly. Prebored holes should be used except for small screws in soft wood. Lead hole for the shank should be the same diameter as the shank; lead hole for the threaded portion should be 40 to 70% of shank diameter in such species as northern white pine, 60 to 75% in Douglas fir and southern yellow pine, and 65 to 85% in white oak. The larger figures in each range apply to larger screws. Soap or other lubricant should be used on screws, and lead holes may be slightly larger than indicated if the lag bolts are of excessive length.

Withdrawal Resistance of Lag Bolts. Safe load for a lag bolt inserted into the side grain of the wood is given by

$$P = 1500D^{3/4}G^{3/2} \tag{6}$$

where P is safe load (based on safety factor 5) per inch of penetration, pounds; D is diameter of screw, inches (see Table 5 for usual sizes); and G is specific gravity of wood species (see Table 3 for values of G and $G^{3/2}$). For screws inserted into the end grain the safe load is about 75% of the value in eq. 6.

Lateral resistance of lag bolts may be expressed by an equation of the form

$$P = K_3D^2 \tag{7}$$

where P is the safe lateral load of a lag-screw joint of dry wood, with the bearing surfaces parallel to the grain of the wood, pounds; K_3 is a constant which depends on the wood species (see Table 3); and D is the shank diameter of the screw, inches (see Table 5).

Equation 7 applies to joints having cleat thicknesses 3½ times the shank diameter of the screw, and depth of penetration of the screw in the main members varying from 11 to 7 times the diameter, depending on the wood species. The higher penetration applies to the softer woods. When metal cleats are used, the loads may be increased 25%. For further data on lag-screw joints, see Ref. 2.

9. TIMBER-CONNECTOR JOINTS

METHODS OF FAILURE. Wood-framed structures, especially roof trusses, towers, bridges, and trestles, tend to fail at bolted joints. Figure 3 shows the method of failure when the wood is stronger than the bolt. In Fig. 4, where the bolt is stronger than the wood, the joint fails by deforming and splitting the wood. Drawing the bolt up tight creates friction between the surfaces and retards slipping. Shrinkage of the wood decreases the friction.

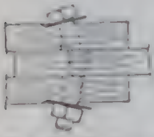

Fig. 3. Failure when wood is stronger than bolt.

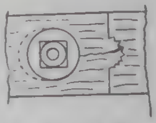

Fig. 4. Failure when bolt is stronger than wood.

BOLTS. Bearing stresses in the wood under a bolt are not uniform but are concentrated at the edges of the timbers, the effect becoming more pronounced as the ratio of length of bolt in the timber to its diameter increases, and as the ratio of wood strength to bolt strength increases. Basic stresses given in the last two columns of Table 3 may be used for L/D ratios up to 2 with any combination of bolt and wood species. With the softer wood species and higher strength bolts, these basic stresses can be used for higher L/D ratios. Beyond the limiting L/D ratios modifying factors must be used. For complete data, see Ref. 1.

TIMBER CONNECTORS. Modern connectors of many types and variations have been patented. Their purpose is to furnish a positive resistance to slip between the faces of the joint, like a dowel or key. The more important of these are illustrated in Figs. 5, 6, and 7. The split-ring connector (Fig. 5) may be straight sided or beveled and is fitted into precut grooves in the adjoining faces of the joint. The toothed or Alligator joint (Fig. 6) is forced into the timbers as the members are pressed or clamped together. Claw plates (Fig. 7) fit into prebored recesses and have short teeth which are forced further into the wood. They are used singly in making timber-to-metal connections, or in matched pairs (male and female) for timber-to-timber connections. Data on the strength of these connectors are found in Ref. 3.

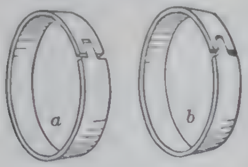

Fig. 5. Split-ring connector.

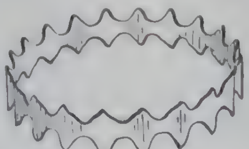

Fig. 6. Toothed timber connector.

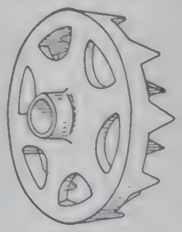

Fig. 7. Claw-plate timber connector.

MECHANICAL SPRINGS

DEFINITIONS AND TYPES OF SPRINGS. A mechanical spring may be defined as an elastic body or resilient member whose primary function is to deflect or distort under load; it recovers its original shape when released after being distorted. The more important types of springs are:

Helical compression or tension springs are made of bar stock or wire coiled into a helical form, the load being applied along the helix axis. In a compression spring, the helix is compressed; in a tension spring, it is extended.

Helical torsion springs are similar in form to the helical compression spring but loaded by a torque about the helix axis.

Leaf springs are composed of flat bars of varying lengths clamped together so as to obtain greater efficiency and resilience (automobile leaf springs). Such springs may be *full-elliptic, semi-elliptic,* or *cantilever.*

Spiral springs consist of flat strip wound in the form of a spiral (clock springs) and are loaded in torsion.

Belleville springs are composed essentially of coned disks which may be stacked up to give a variety of spring load-deflection characteristics.

1. HELICAL COMPRESSION SPRINGS

BASIC THEORY AND FORMULAS. Probably the most widely used type of spring in the mechanical engineering field is the helical round-wire compression spring (Fig. 1). Among the reasons for the wide use of this type of spring are low cost, compactness, and efficient use of material.

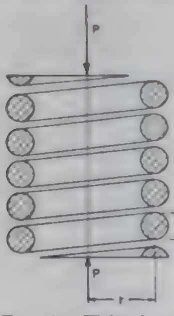

FIG. 1. Helical compression spring.

As shown in Fig. 1, a spring loaded by an axial load P may be considered essentially as a bar under a torsion moment Pr. On this basis, the torsional shearing stress S_s will be equal to the moment divided by the section modulus. This gives

$$S_s = \frac{16Pr}{\pi d^3} \tag{1}$$

where r = mean coil radius and d = bar or wire diameter. This stress, which is widely used in spring design, is frequently termed the *uncorrected* stress, since it does not correct for effects of bar or wire curvature or for the effects of direct shear loading (which will be discussed further below). In spite of its simplicity, this formula is surprisingly good as a criterion of static load-carrying ability without excessive set.

Spring Deflection. If the spring is considered essentially as a bar subjected to a torsion moment Pr the deflection δ becomes

$$\delta = \frac{64Pr^3n}{Gd^4} \tag{2}$$

where n = number of active coils and G = modulus of rigidity of material, pounds per square inch. For the usual compression spring with ends squared and ground, approximately one inactive coil may be taken at each end, giving a value for n equal to the total number of coils minus 2. However, slightly better accuracy will be obtained in most cases by using a figure of 1.75 instead of 2 (Ref. 1, p. 158).

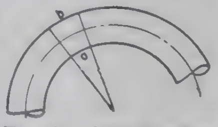

FIG. 2. Coil of helical spring.

For most carbon steel springs (music wire, oil-tempered wire) the modulus G may be taken as about 11.5×10^6 psi whereas for hot-wound springs, heat-treated after coiling, $G = 10.5 \times 10^6$ psi is usually preferred. (See Table 8, p. 11-18, for further values of G for different spring materials.)

The *spring rate* (or scale) in pounds per inch deflection is

$$\frac{P}{\delta} = \frac{Gd^4}{64r^3n} \tag{3}$$

Parts of the data in this section have been abstracted from the author's *Mechanical Springs* (Ref. 1).

Correction for Curvature and Direct Shear. In deriving eq. 1, neither the effect of the direct shear load P on the spring nor the effect of curvature of the bar or wire is considered. Referring to Fig. 2, which represents a plan view of the coil of a helical spring, the fiber length at a on the inside of the coil is considerably shorter than that at b on the outside.

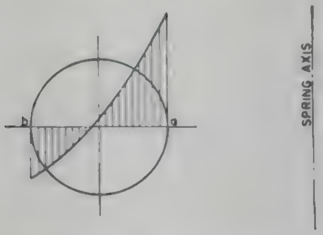

FIG. 3. Elastic shearing stress distribution across transverse diameter of helical spring of small index.

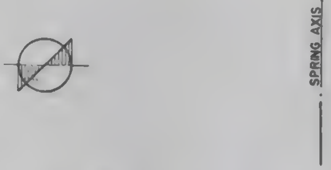

FIG. 4. Elastic shearing stress distribution across transverse diameter of helical spring of large index.

Consequently when two neighboring radial cross sections are rotated with respect to each other, the unit shearing displacements are much greater at a than at b. Thus *below the elastic limit*, the stress distribution across the transverse diameter of the spring will be something like that in Fig. 3, with a peak at the inside of the coil at a for small index springs, i.e., springs with a small ratio of coil-to-wire diameter. For a spring of large index the torsional stress distribution will approximate the linear type for a straight bar in torsion (Fig. 4).

It should be noted that the elastic stress distributions shown in Figs. 3 and 4 apply strictly only to cases where the springs are initially free of stress and where the loading is such that the elastic limit of the material is not exceeded. Where springs are cold-set (as is often done in manufacture) yielding of the material occurs so that at high loads the stress distribution is somewhat as shown in Fig. 5, the result being a more uniform distribution of stress. At the same time residual stresses are induced which subtract from the load stress at lower loads.

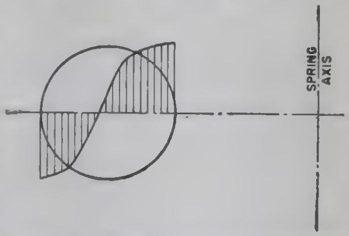

FIG. 5. Stress distribution across transverse diameter in small index spring at high loads after yielding has occurred.

To calculate the elastic stress S_s' at point a (Fig. 3) at the inside of the coil, the stress given by the usual formula (eq. 1) may be multiplied by a factor K (usually known as a curvature correction factor) which depends on the spring index $c = 2r/d$ (Ref. 2). This gives

$$S_s' = K \frac{16Pr}{\pi d^3} \tag{4}$$

where

$$K = \frac{4c - 1}{4c - 4} + \frac{0.615}{c} \tag{5}$$

A plot of the correction factor K versus spring index $2r/d$ is given in Fig. 6. The stress calculated in this way is frequently called the *corrected* stress to distinguish it from the *uncorrected* stress figured from eq. 1.

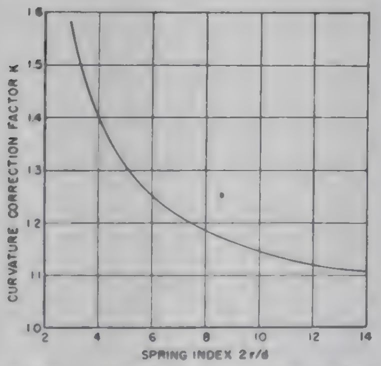

FIG. 6. Correction factor K for helical springs.

More accurate equations have been developed to take into account the elastic effects due to curvature, direct shear, and pitch angle (Ref. 3). For most practical springs these differ but slightly from the results given by eq. 4.

In manufacture, compression springs are frequently *cold-set*, i.e., coiled to a greater free height than is specified and then compressed sufficiently to cause a permanent set and a reduction in free height to the specified value. This operation, also known as *scragging* or *presetting*, results in yielding and plastic flow at points of maximum stress. Hence the corrected stress calculated by using eq. 4 will not usually exist in cold-set springs, i.e., the actual peak stress is lower than the calculated value. However, where fatigue loading is involved, if P is taken as load *range*, i.e., the difference between minimum and maximum load during a cycle, the corrected stress S_s' of eq. 4 will be equal to the stress *range*. This is of importance where fatigue loading is present.

If the average stress due to the direct shear load P is added to the uncorrected stress (eq. 1), the resultant stress S_s'' is

$$S_s'' = K_s \frac{16Pr}{\pi d^3} = K_s S_s \tag{6}$$

where $K_s = 1 + (0.5/c)$ and c = spring index. This formula, sometimes used for static loading, yields somewhat more conservative results than eq. 1.

DESIGN METHODS AND WORKING STRESSES. For purposes of design, helical-spring applications may conveniently be divided into three groups, each of which requires a somewhat different method of approach for best overall results. They are:

(1) Static loading (load on spring steady or applied less than, say, 1000 times).

(2) Intermediate loading (load applied, say, 1000 to 100,000 times during the life of the spring).

(3) Fatigue or endurance loading (load applied a million times or more).

(1) Static Loading (Load Steady or Infrequently Repeated). This category includes cases where the load is steady, or applied less than, say, 1000 times during the life of the spring. Such applications include circuit-breaker springs operating infrequently, safety-valve springs, and springs used to apply gasket pressure. In such cases failure by fatigue fracture is not a problem, the chief concern being to avoid excessive set or creep. The choice of working stress thus depends to some extent on whether a small amount of set may be tolerated; if so, a higher working stress may be used than would be the case otherwise. The problem of creep or set is also aggravated by temperatures above about 250 F for ordinary steel springs (p. 11-05).

At the present time, it is the consensus of most spring authorities that the stress augments due to curvature and direct shear may be neglected when calculating springs for static loading, i.e., that the *uncorrected* stress (eq. 1) may be used. Where somewhat more conservative design is required and the spring index is small, it is suggested that stresses for static loading be figured by using eq. 6, which takes into account the stress augment due to direct shear loading but not that due to curvature.

Working Stresses Used in Practice—Static Loading and Normal Temperature. As an example of the extremely high working stresses for helical springs which can be used in practice where space is at a premium, the curves of Fig. 7 have been taken from data published by the Society of Automotive Engineers (Ref. 4). They represent *uncorrected* allowable stress values (eq. 1) for various spring materials and various wire or bar sizes for helical compression springs used in ordnance applications, where a relatively short spring life is ordinarily required. These curves apply only under the following conditions: springs cold-set and shot-peened for sizes over $^1/_{16}$ in.; normal temperature operation; spring index between 4 and 9. Where these conditions are not fulfilled stresses should be lower.

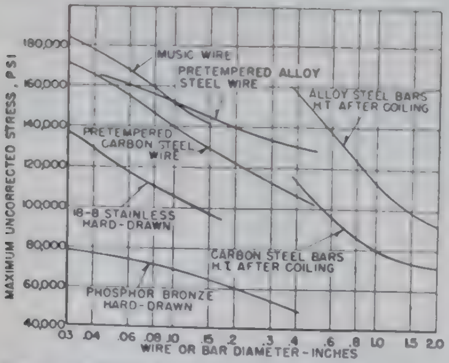

FIG. 7. Stresses in compression springs for ordnance applications where space is limited and only short life is required. (Data from *SAE Manual*, Ref. 4)

It should be emphasized that the stress values of Fig. 7 are to be considered as *maximum* values which may be used where necessary when space is at a premium and where only limited life is expected. Where fatigue loading is present (as in automotive valve springs) the use of such stresses would generally result in early fatigue failure. For industrial applications where more space is usually available, it is suggested that about 25% lower stresses than those given in Fig. 7 be used even for infrequent or static loading.

As a further example of working stress values used in practice, suggested stress values by Associated Spring Corp. (Ref. 5) are given in Table 1 for various spring materials. These values apply to springs under occasional loading at normal temperature. In this case the working stress values are taken 20% higher when using the corrected stress formula (eq. 4).

It may be noted that the uncorrected stress values given in Table 1 are, in general, about 20 to 25% lower than those listed in Fig. 7.

Table 1. Safe Working Stress for Helical Springs

(Under occasional loading only)

Material	Wire Size, in.	Corrected Stress, psi (eq. 4)	Uncorrected Stress, psi (eq. 1)
Music wire	.015	180,000	150,000
	.060	155,000	129,000
	.156	128,000	107,000
Chrome-vanadium wire	.040	157,000	131,000
	.100	140,000	117,000
	.500	115,000	96,000
Oil-tempered or carbon valve spring wire	.020	164,000	137,000
	.100	127,000	106,000
	.500	92,000	77,000
18-8 Stainless wire	.025	122,000	102,000
	.150	93,000	78,000
	.500	70,000	58,000
Phosphor-bronze wire	.025	77,000	64,000
	.150	65,000	54,000
	.500	46,000	38,000

Static Loading—Elevated Temperature. It has been found that at relatively low operating temperatures (as low as 250 F) considerable relaxation or set, depending on stress and temperature, will take place in helical springs loaded continuously. Thus a spring clamped between parallel plates at elevated temperature will gradually lose part of its load over a period of time. In such cases very much lower stresses than those given in Table 1 must be used.

Tests by Zimmerli (Ref. 6) indicate that at 80,000 psi corrected stress (72,000 uncorrected) music-wire springs will lose around 2 to 3% of their initial loads at 250 F and 7% at 350 F within three days. At 100,000 psi (90,000 uncorrected), load losses in three days of about 5% at 250 F and 10% at 350 F may be expected. Extrapolated relaxation curves (Ref. 7) for music-wire springs indicate that in a year or so two or more times as much relaxation will occur as occurred in three days. Hence it appears that for operation in the range of 250 F to 350 F and uncorrected stresses around 90,000 psi music-wire springs may lose around 20% of initial load in about a year's time because of relaxation. For this reason it is in general desirable to use springs of 18-8 stainless steel wire above 250 F since tests show that they will have much lower load losses than the music-wire springs.

At temperatures of 350 to 500 F the superiority of stainless steel over music-wire or carbon-steel springs is even more pronounced. Extrapolated relaxation data available (Ref. 7) indicate that at 300 F and 90,000 psi uncorrected stress 18-8 stainless-steel springs will lose around 8% load in one year as compared with about 4% in three days. At 450 to 500 F this loss may be as high as 12 to 14% in one year. This relaxation should be considered in design, or steps should be taken to reduce it.

Thus, for applications at temperature above 500 F, the use of an alloy such as Z-nickel or Inconel may be advisable. The spring manufacturer should be consulted in such cases. The relaxation or set occurring during operation may be reduced by loading the springs under temperature at a load somewhat above the working load for a few days. In this manner a considerable part of the initial set is removed; hence less will occur under subsequent loading.

(2) Intermediate Loading (Load Applied 1000 to 100,000 Times). Perhaps the majority of spring applications fall in this category, which includes springs subject to the peak load, say, 1000 to 100,000 cycles during their lives. Examples are automobile suspension springs and springs used in circuit-breaker mechanisms. Such springs would be considered to be under a more severe application than where only static loading is involved; at the same time the condition is not so severe as where fatigue loading is involved.

An estimate of the amount of increase in allowable stress where springs are subject to 100,000 or fewer cycles of load application may be obtained by using the fatigue-test results reported by Edgerton (Ref. 8). These test results (Fig. 8) were obtained on carbon-steel springs ($^3/_4$ bar diameter, index 5) tested in a zero to maximum stress range. In this curve the corrected stress range is plotted against number of cycles to failure (log scale), the trend of the average being indicated by the full line. From this it is seen that for a life of 100,000 cycles the allowable stress is about 1.5 times the stress for a life of one million cycles. Higher values would be expected for centerless-ground bar springs, shot-peened, of index 5, and lower values for springs of higher indexes.

For applications involving a limited number of cycles, the following conservative method of design may be used. The stress at maximum load should be figured as uncorrected stress (i.e., without curvature correction) and should not exceed the allowable value for static loading (see p. 11-04). The stress range, obtained from the upper and lower limits of the load range, should be figured as a corrected stress (eq. 4), and this should be compared with the endurance range for the required number of cycles using curves of the type shown in Fig. 9. For small numbers of cycles and for small indexes (i.e., larger curvature correction factors) this method will probably err on the safe side, since as the number of cycles is reduced the condition tends to approach a static load condition where curvature correction may be neglected. Further test data are needed to throw light on this question.

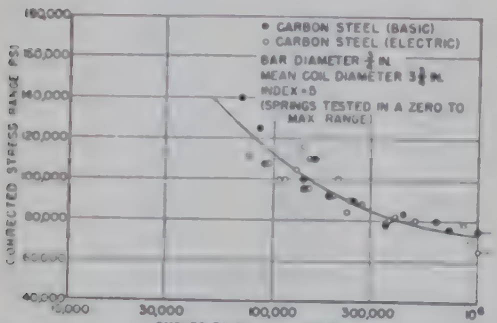

FIG. 8. Results of fatigue tests of hot-wound heavy helical springs. (Edgerton, *Trans. A.S.M.E.*, Oct. 1937, and *Progress Report* 3 of A.S.M.E. Spring Committee, Ref. 8)

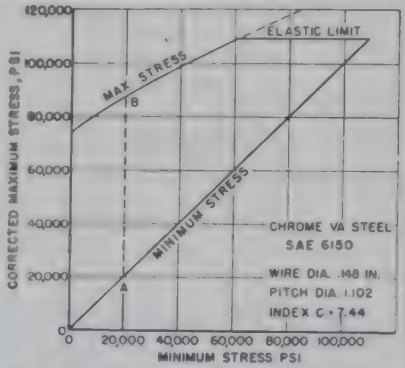

FIG. 9. Typical endurance diagram for helical compression springs. (Zimmerli, *University of Michigan Engineering Research Bull.* 26, Ref. 10)

An example of working-stress values suggested for average service conditions is given in Table 2, based on data published by American Steel and Wire Company (Ref. 9).

Table 2. Recommended Maximum Corrected Stresses for Helical Compression and Extension Springs Under Average Service Conditions *

	Kind of Wire (Plain Carbon Steels)			
Wire Diameter, in.	Music	Tempered	Hard-drawn	
0.020 to 0.030	100,000	100,000	90,000	
0.031 to 0.092	90,000	100,000	80,000	
0.093 to 0.176	90,000	90,000	80,000	
0.177 to 0.282	....	90,000	70,000	
0.283 to 0.436	....	85,000		
0.437 to 0.624	....	80,000		If OD greater than 3 in.—(cold-wound)
	....	90,000		If OD less than 3 in.—(hot-wound)
0.625 to 0.874	....	90,000		Hot-wound
0.875 to 1.249	....	80,000		
1.250 to 1.5	....	80,000		

* Defined as noncorrosive atmosphere, temperatures not over 150 F, slowly varying or static loads. All stresses in pounds per square inch.

Average service conditions in this case (Table 2) are defined as noncorrosive atmosphere, temperature not over 150 F, and under relatively slowly varying loads. Since curvature correction is included in the stress figures of Table 2, it will be noted that for average spring indexes where curvature correction is about 20%, these values are equivalent to lower uncorrected stresses than those of Fig. 7 for ordnance applications.

EXAMPLE 1. COMPRESSION SPRING FOR CIRCUIT BREAKER. A spring used in a circuit breaker is designed for a life of approximately 100,000 cycles. Dimensions are: OD = $5/8$; $d = 0.071$ (music wire); $r = 0.277$ in.; index = 7.8; 9 active turns; free length 2 1/4 in.; closed length 1 3/32 in. In operation the load varies from a minimum of 11.7 lb to a maximum of 27.3 lb. From eq. 1, the *uncorrected* stress at maximum load is

$$S_s = \frac{16 \times 27.3 \times 0.277}{\pi(0.071)^3} = 108{,}000 \text{ psi}$$

The load *range* between maximum and minimum load is 27.3 − 11.7 = 15.6 lb, and the corrected stress *range* from eq. 3, taking $K = 1.19$ from Fig. 6 for $c = 7.8$, is

$$S_s' = \frac{16 \times 15.6 \times 0.277 \times 1.19}{\pi(0.071)^3} = 73{,}000 \text{ psi}$$

In this case, it is seen that the peak uncorrected stress is somewhat below that listed in Table 1 for this size wire. Also the stress range is below that to be expected from endurance tests of this size wire for 100,000 cycles life

EXAMPLE 2. CUP SPRING FOR TURBINE LOCOMOTIVE DRIVE. An example of the design of heavy springs for intermediate loading conditions is given by the springs used in a turbine locomotive as the flexible element between the arms of a spider pressed on the axle and the gear driven by the turbine. These springs are hot wound from chrome-vanadium steel bars, centerless-ground, shot-peened, and magnaflux-tested. Dimensions are: OD 3.56 in.; bar diameter 0.870 in.; index 3.1; free height 10.51 in.; 8 3/4 active turns; solid load 7650 lb; solid deflection 1.59 in. Maximum uncorrected stress on the spring with coils solid is 80,000 psi, corresponding to 57% adhesion between wheel and rail, which occurs only at rare intervals. For normal starting conditions, where 30% maximum adhesion between wheel and rail is assumed, the uncorrected stress will be 42,000 psi and the corrected stress 65,000 psi. This stress range of 63,000 psi is around half the expected endurance range for 100,000 cycles for shot-peened springs of index 3 (Fig. 8). Under normal operating conditions with 18% adhesion the corrected stress in this spring will be 39,000 psi.

(3) Fatigue or Endurance Loading (Load Applied a Million Times or More). Examination of springs which have failed due to fatigue or repeated loading shows that in most instances the fracture starts at the inside of the coil or at the point where the range of stress is a maximum. The stress *range* at this point may be calculated with sufficient accuracy using the corrected stress formula (eq. 4), taking P equal to load range, i.e., difference between maximum and minimum load. On this basis it appears reasonable, where fatigue loading is involved, to calculate the stress range as a corrected stress.

Because of lack of sensitivity of some materials to stress concentration (as represented by curvature effects) the endurance ranges calculated by this method will probably be higher for the lower-index springs (small $2r/d$) than for the high-index springs, the difference depending on the material. Available data indicate that this difference will be considerably greater for heavy hot-wound springs (Ref. 8) than for small springs of valve-spring wire. Thus if the endurance range calculated as a corrected stress is determined from tests of large index springs it will, in general, be safe to apply the results to lower index springs of the same material and wire size. However, caution should be exercised in applying the results of fatigue tests on low- or medium-index springs to those of high index of the same wire size, since the latter will frequently show lower endurance range values. Also in general the endurance range of the material decreases somewhat as the maximum stress of the range increases, and for best results this should be considered in design. In other words, for a load range from zero to maximum, the endurance range will be appreciably greater than for a load range from, say, half the maximum to the maximum.

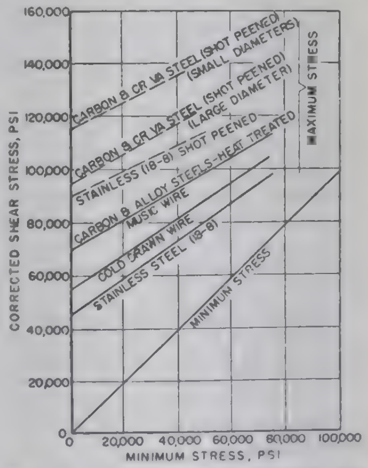

FIG. 10. Approximate endurance diagrams for good-quality helical compression springs.

A typical endurance diagram for a helical spring made of chrome vanadium steel wire of 0.148 in. diameter, index 7.44, is shown in Fig. 9. This curve, based on tests by Zimmerli (Ref. 10), represents the maximum and minimum corrected stress limits for a spring under fatigue loading. The limiting stress range is read vertically between the line representing maximum stress and one representing minimum stress. Thus a spring operating in a fatigue range between 20,000 and 87,000 psi corrected stress would be represented by the vertical dashed line AB. A range within these limits (say from 20,000 to 70,000 psi) would not be expected to cause failure. It should be noted that this applies to one case (wire size 0.148 in., index $c = 7.44$). For other wire sizes or indexes the curve could be appreciably different.

Approximate endurance diagrams which may be expected from good-quality helical compression springs of different materials are shown in Fig. 10. In all cases, the limiting endurance range is read vertically between the lower line representing minimum stress and the upper line corresponding to the given spring material. These curves hold roughly for springs having indexes between 5 and 10. Since these curves represent rough average values, considerable deviation in individual instances may be noted. Sometimes higher values than those of Fig. 10 may be obtained for small-index springs. The effect of shot peening in raising the endurance limit is shown by the three upper dashed lines. It should be emphasized that in practical design lower stress ranges than those indicated by these endurance values should be used in order to provide a factor of safety. This factor of safety may range from 1.25 to 2, depending on the seriousness of failure and on the accuracy of the fatigue-test data available.

Several examples of working stress ranges where fatigue loading is involved (automotive valve springs) are given in Ref. 10. The corrected stress ranges in such applications are around 30,000 to 50,000 psi while the peak stress may vary from 60,000 to 83,000 psi, corrected, for springs not shot-peened. (Actually the above figures are nominal stresses based on valve lift; at high speeds of operation the actual peak values may be greater due to vibration and surging.) By using shot peened springs a higher factor of safety is obtained.

As a further example of working stresses used in practice where fatigue is involved, the stresses given in Table 3 are used as a basis for design for severe service involving fatigue loading by Westinghouse Electric Corporation. These stresses, which are corrected values, apply to music or oil-tempered wire in the smaller sizes and to hot-wound springs, heat-treated after forming in the larger sizes. This table is intended to be used primarily as a guide in spring selection; in many cases higher values may be used if a careful analysis of the application is carried out.

Table 3. Working Stresses for Severe Service—Helical Compression Springs *

Diameter of Wire, in.	Working Stresses
Up to .085	60,000
Above .085 to 0.185	55,000
Above .185 to 0.320	48,000
Above .320 to 0.530	42,000
Above .530 to 0.970	36,000
Above .970 to 1.5	32,000

* For springs made of music or oil-tempered wire, in smaller sizes and hot-wound springs, heat-treated after forming, in larger sizes. For phosphor-bronze 50% of these values, and for stainless steel 75% of these values, are used. Table does not apply where corrosion effects are present. Values represent *corrected* stresses.

SPRING TABLES. Based on Corrected Stress. To facilitate spring selection in practical design Table 4 may be used (Ref. 11). For each OD and wire size two figures are given: an upper one representing load in pounds at 100,000 psi *corrected* stress and a lower one representing spring scale in pounds per inch per single coil based on a shear modulus G of 11.5×10^6 psi. For any actual spring, the spring scale per coil given in the tables must be divided by the number of active coils. This scale is independent of the load. To obtain the spring scale per coil at any modulus G, the values in the table should be multiplied by $11.5 \times 10^6/G$.

It should be noted that the figure of 100,000 psi corrected stress is used mainly for convenience and is not necessarily the working stress. For any other corrected stress S_s', the loads given may be multiplied by the ratio $S_s'/100{,}000$. Also the loads given in the table may be considered to represent load *ranges* at corrected stress *ranges* of 100,000 psi.

If it is desired to determine the load at an *uncorrected* stress of 100,000 psi, the loads given in Table 4 should be multiplied by the correction factor K (Fig. 6) corresponding to the spring index.

Example 3. Assume that a compression spring is required for a mechanism to give 200 lb at a deflection of 1.0 in. operating under fatigue conditions. The required spring scale is thus $200/1.0 = 200$ lb per in. The space available is such that an OD of 2 in. may be used. From Table 4, for 0.283-in. wire and 2 in. OD, load at 100,000 psi corrected stress is 415 lb, and spring scale per coil is 1820 lb per in. Since this spring is to operate under severe conditions, the allowable stress will be taken from Table 3, and is 48,000 psi for 0.283 wire. Load at 48,000 psi corrected stress is $0.48\ (415) = 200$ lb. Since the scale wanted is 200 lb per in., number of active coils $= 1820/200$ or approximately 9. Total number of coils would be around 10 1/2 to 11. This would require a spring of about $1.1\ (10.5)(0.283) + 1.0 = 4.27$ in. free length, allowing 10% extra length for space between the turns when the spring is compressed at a load of 200 lb. The length at a load of 200 lb would be $4.27 - 1.0$ or 3.27 in. and the solid length about 10% less or about 2.94 in.

Tables for Static Loading. Where springs are *statically loaded* Table 5, based on 100,000 psi stress calculated using the factor K_s, may be used. (This factor takes into account direct shear but not curvature effects.) Loads P and deflections per turn y at a stress of 100,000 psi are given for various wire sizes and outside coil diameters. The deflection y is based on a shear modulus of 11.4×10^6 psi. Although stresses of 100,000 psi may be used in many cases, this figure is used in Table 5 merely for convenience. For any other stress

S_s, loads P and deflections y should be multiplied by the ratio $S_s/100{,}000$, and for any other modulus G, deflections y should be multiplied by $11.4 \times 10^6/G$. Interpolation for intermediate wire sizes or OD values may be used with sufficient accuracy for most purposes.

In general, for most springs, loads and deflections per turn as given in Table 5 are about 5 to 10% lower than they would be if calculated by the uncorrected stress formula (eq. 1). This table thus represents slightly more conservative ratings for the smaller indexes than if the uncorrected stress values were used. To find loads and deflections at 100,000 psi uncorrected stress, values of P and y given in the table should be multiplied by the factor $K_s = 1 + (0.5/c)$, where c = spring index.

Table 5. Loads * and Deflections per Turn for Statically Loaded Helical Springs

* Stress of 100,000 psi is used for convenience. For any other stress S_s, values of P (load in pounds) and y (deflection per turn) should be multiplied by $S_s/100,000$. Deflections are based on a torsion modulus $G = 11.4 \times 10^6$ psi. For any other value of G, deflections given should be multiplied by the ratio $11,400,000/G$.

To facilitate approximate determination of loads and deflections the charts of Figs. 11 and 12 may be used. In Fig. 11 the ordinate represents load at 100,000 psi torsion stress (calculated from eq. 6, which includes effects of direct shear but not of curvature) while the abscissa represents wire diameter. Each curve represents a given outside diameter of the spring. Thus for a wire size of 0.090 in. and an outside diameter of 1/2 in. the load at 100,000 psi stress is 61 lb. In Fig. 12 the deflections per turn, represented by the ordinates, are plotted against wire diameter for various outside coil diameters. Thus in this figure for a wire size of 0.106 in. and a coil outside diameter of $1/2$ in., the deflection per turn is 0.036 in. Results from the charts of Figs. 11 and 12 usually show a small error, but they are sufficiently accurate for most practical purposes.

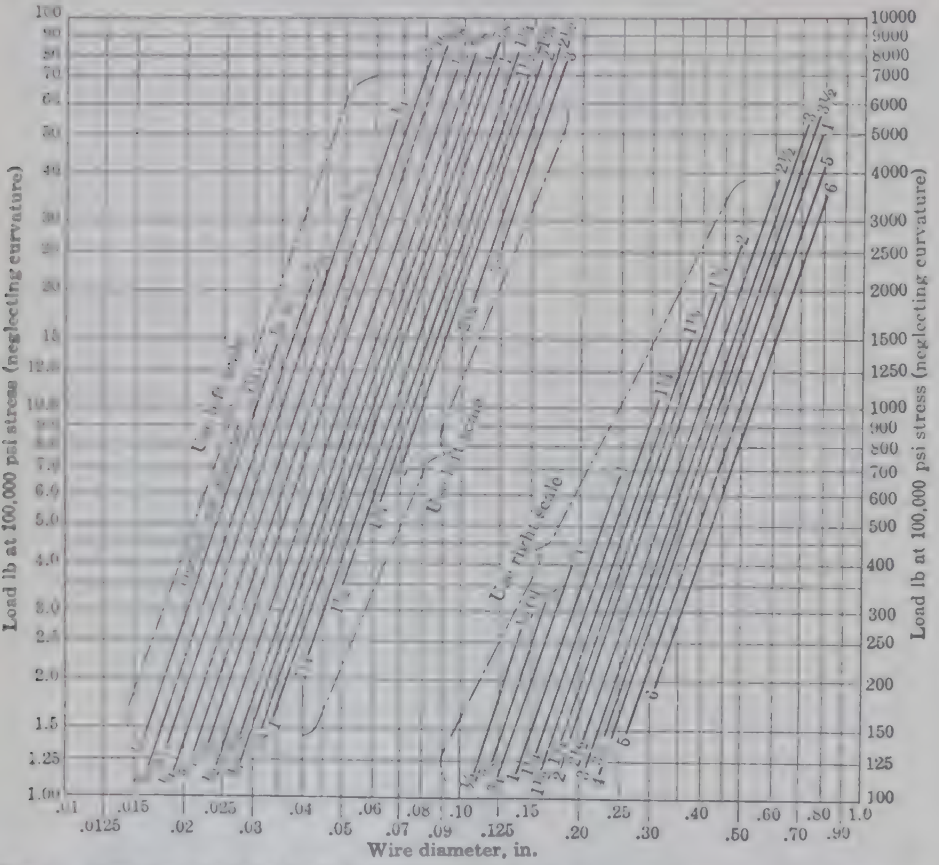

FIG. 11. Chart for calculating loads in statically loaded helical springs, based on 100,000 psi stress. For any other stress, S_s, load values must be multiplied by $S_s/100{,}000$. (Reproduced by permission from *Machine Design*, July 1942)

BUCKLING OF COMPRESSION SPRINGS. Experience shows that if the free length is too long, a compression spring may buckle as a column at relatively light loads. This phenomenon is essentially similar to the buckling of long slender columns when the load exceeds the critical load. In practical design it is necessary to guard against this by choosing the spring proportions in such a way that the buckling load will always be greater than any load encountered in service, or, if this is not practical, guides must be provided to prevent sidewise motion.

The calculation of critical buckling loads for helical springs involves essentially the same methods as those used in column theory. However, the analysis in the case of the spring differs from that used in ordinary column theory in that it is necessary to consider the decrease in length under load. In the case of the usual steel column, on the other hand, this decrease is small and may be neglected. Besides the change in length under load, it is also necessary to consider the deformations of the spring due to lateral shearing forces. An analysis taking these factors into account has been carried out (Ref. 12). This analysis shows that the critical deflection at which buckling occurs depends on the ratio between free length l_0 and mean coil diameter $2r$ and on the method of fastening the spring ends, i.e., whether fixed or hinged. In Fig. 13*a* a spring with fixed ends is indicated; in Fig. 13*b*, one with hinged ends. In Fig. 14, curve *a* shows the ratio of the *critical buckling deflection* to *free length* plotted against ratio of free length l_0 to mean coil diameter, for a spring with hinged ends (Ref. 12). Curve *b* represents the built-in end condition. Actual helical springs compressed between plates which are approximately parallel will usually show results intermediate between these two cases. For this reason a conservative method of design is to use the hinged-end curve although this may yield somewhat low values for the buckling load. The critical buckling load for any spring is the critical deflection multiplied by the spring rate (eq. 3). Tests (Ref. 12) show good agreement with the curve for springs with hinged ends. In practical springs some deviation from these theoretical curves must be expected because of uncertainty as to the end condition and the effects of eccentricity of loading. From Fig. 14 it is seen that if the ratio $l_0/2r$ between free length and mean coil diameter is less than about 2.7 for the hinged-end condition, no buckling

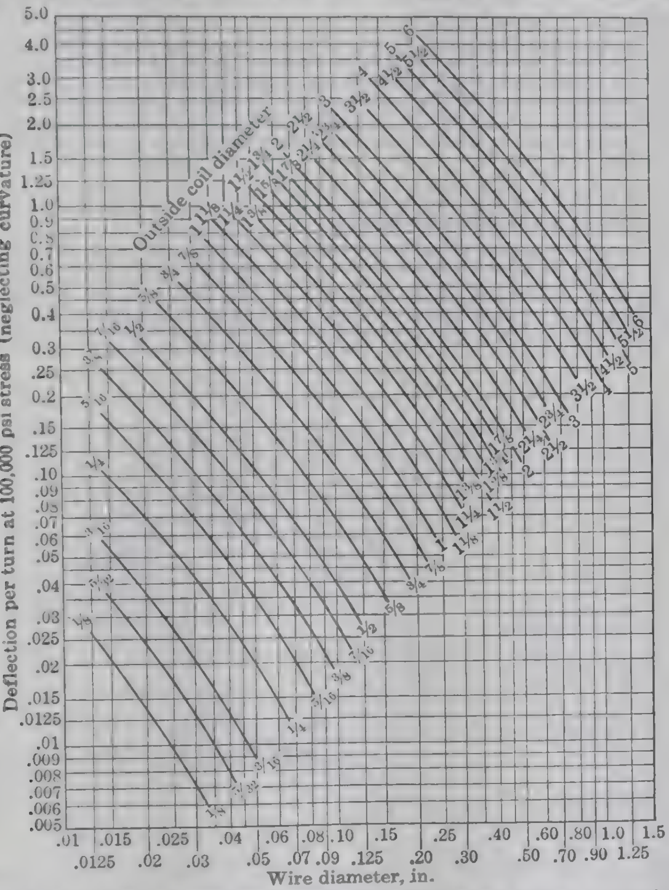

FIG. 12. Chart for calculating deflections in statically loaded helical springs of round wire, based on 100,000 psi stress and 11.4×10^6 psi torsional modulus. For any other stress, S_s, deflection values must be multiplied by $S_s/100{,}000$; for any other modulus, G, values must be multiplied by $11{,}400{,}000/G$. (a) FIXED ENDS

(b) HINGED ENDS

FIG. 13. Springs with fixed and hinged ends.

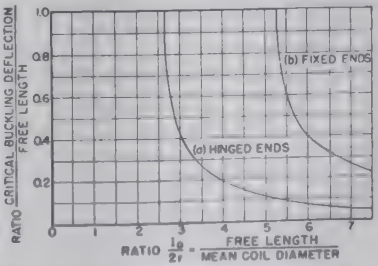

FIG. 14. Curves for finding critical buckling deflection. Buckling load = buckling deflection × spring rate. (Data from Haringx, Ref. 12)

will occur before the spring is compressed solid. For the built-in end condition, buckling will not occur for a ratio $l_0/2r$ less than about 5.3.

Example 4. As an example of the use of the curve of Fig. 14 for determining danger of buckling, assume a steel helical compression spring of the following dimensions: free length, $l_0 = 6$ in., mean coil radius $r = 0.75$ in., $l_0/2r = 4$, outside diameter = 1.75 in., wire diameter 0.25 in., active turns $n = 12$. From Table 4, p. 11-10, for these dimensions the spring rate is 1667/12 = 139 lb per in. Assuming that the spring has hinged ends, from Fig. 14 the ratio of critical deflection to free length for $l_0/2r = 4$ is 0.2. Thus buckling for such a spring would occur at a deflection $0.2l_0 = 0.2 \times 6 = 1.2$ in. or at a load of 1.2 × 139 lb per in. = 167 lb. However, if this spring were rigidly clamped to two parallel plates and then loaded so that the built-in end condition were realized, no buckling would be expected at any practical deflection.

LATERALLY LOADED HELICAL SPRINGS. In practice helical springs are sometimes loaded laterally while being compressed, as indicated in Fig. 15. Examples of such applications are certain types of railway trucks and spring supports for refrigerator compressors. For such springs it will be found that in general the lateral deflection δ_l due to the load Q, increases as the axial load P increases. To calculate this lateral deflection δ_1, the following formula may be used. This applies to steel springs where the modulus of elasticity E is 30×10^6, and modulus of rigidity $G = 11.5 \times 10^6$ psi.

$$\delta_1 = \frac{CQnr}{10^6 d^4}\left[0.408l^2 + 2.12r^2\right] \tag{7}$$

where n = number of active coils; r = mean coil radius; d = wire diameter; l = compressed length, Q = lateral load (Fig. 15); C = a factor which depends on the ratio of free length to mean coil diameter and on the ratio δ/l_0 between compression due to axial load P and free length. A chart for determining the factor C is shown in Fig. 16 (Ref. 12). It should be emphasized that because of imperfect clamping of the ends and other deviations from the idealized case assumed in deriving eq. 7 and Fig. 16, considerable difference may occur between test and theoretical values for lateral deflections. (See Ref. 13.) Also because of these lateral deflections, additional stresses are set up (Ref. 1, p. 180) which should be allowed for in design.

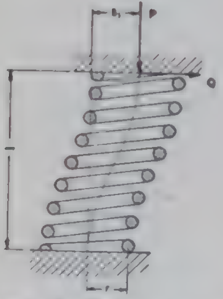

Fig. 15. Spring under combined lateral and axial loading.

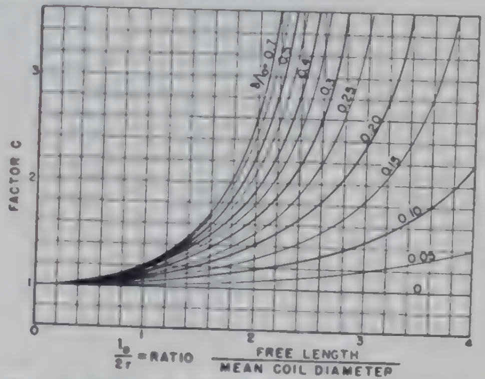

Fig. 16. Chart for finding factor C for lateral deflections. (Data from Haringx, Ref. 12)

Example 5. A laterally loaded steel spring has the following dimensions: OD = 5 in.; mean coil diameter $2r = 4.25$ in.; bar diameter $d = 3/4$ in.; free length $l_0 = 9.5$; $l_0/2r = 2.24$; and active coils $n = 8$. Using these dimensions in eq. 3, the spring rate P/δ is 732 lb per in.

Assume that the axial load P on this spring is 2400 lb and the lateral load $Q = 200$ lb. Then the axial deflection δ at this load is 2400/732 = 3.28 in. Compressed length $l = 9.5 - 3.28 = 6.22$ in. The ratio δ/l_0 between deflection and free length is 3.28/9.5 = 0.345. From the chart of Fig. 16 for $\delta/l_0 = 0.345$ and $l_0/2r = 2.24$ the factor $C = 2.15$. Using this value and taking $Q = 200$ lb, we find from eq. 7 the lateral deflection $\delta_1 = 0.59$ in. In this case the lateral deflection is about twice the value obtained for a very small axial load where C will be approximately 1.

OTHER DESIGN CONSIDERATIONS. Allowance for End Coils. In forming the usual compression spring, about three quarters of a turn is tapered near each end. The end may then be squared and ground, or if the taper has been made by forging it is merely squared. For such ends, tests have shown that around 0.8 to 1.0 turn near each end is inactive, or a total of 1.6 to 2 turns. Thus if a spring has 12 turns tip to tip of bar, the active coils may vary from 10 to 10.4 turns. At higher loads the number of inactive turns is reduced because of seating of the end coils. For practical design, an average figure of 1 3/4 inactive coils will usually give satisfactory results (Ref. 1, p. 158). The solid height of the spring will be approximately equal to the number of solid coils (see below) times the bar or wire diameter.

Eccentricity of Loading. If a compression spring of usual design is compressed between two parallel plates as in a testing machine, it will be found that in general the resultant load is not directed along the spring axis but instead is slightly eccentric. The effect of this eccentric loading is to increase the torsional stress on one side of the spring and decrease it on the other. An analysis of the effect of this load eccentricity has been carried out (Ref. 14). The results indicate that the load eccentricity e depends primarily on the number of coils and may be expressed as

$$e = 1.12r\left[\frac{0.504}{N} + \frac{0.121}{N^2} + \frac{2.06}{N^3}\right] \tag{8}$$

In this r = mean coil radius and N = number of solid coils or total number of coils minus 1/2 for the usual type of squared and ground ends. The stress in the spring will be increased approximately in the ratio $1 + e/r$ as compared with the stress in a spring under a purely axial load. This correction is of importance for a spring with a small number of active coils. For example, in the case of a spring with five total coils the correction amounts to about 15%. Because of inaccuracies in forming the end turns, eccentricity values in different springs may vary over a wide range, and eq. 8 should be considered to be very rough.

Effect of Variations in Spring Dimensions. Another factor of importance is the effect of slight variations in spring-wire or coil diameters on load-deflection characteristic of springs. Analysis shows that a 1% change in the mean coil diameter means a 3% change in the load-deflection characteristic, whereas a 1% change in the wire diameter results in a 4% change in the deflection characteristic.

In general it is not practical to hold load-deflection characteristics closer than about 5 to 10% in practical springs except at extra cost.

Allowable variations in commercial spring-wire diameters as listed in ASTM standards for various materials are given in Table 6.

Table 6. Allowable Variations in Commercial Spring-wire Sizes

Material	ASTM Specification Number	Wire Diameter, in.	Permissible Variation, in.
Hard-drawn spring wire	A-227-39T	.028 to .072	±.001
Chrome-vanadium spring wire	A-229-39T	.073 to .375	±.002
Oil-tempered wire	A-231-39T	.376 and over	±.003
Music wire	A-228-39T	.026 and under	±.0003
		.027 to .063	±.0005
		.064 and over	±.001
Carbon-steel valve spring wire	A-230-39T	.093 to .148	±.001
		.149 to .177	±.0015
Chrome-vanadium valve spring wire	A-232-39T	.178 to .250	±.002

In winding springs cold, there is always some "spring-back." In other words, the inside diameter of the spring after winding will be slightly greater than the diameter of the mandrel as a consequence of the elastic and plastic properties of the material; this results in unavoidable variations in coil diameters.

Table 7. Tolerances on Spring-coil Diameters (Close Cold-wound Helical Springs)

Mean Coil Diameter, D, in.	Variations in Diameter, D, in.		
	$D/d = 4$	$D/d = 8$	$D/d = 12$
1/8	±.003	±.0035	±.005
1/8 to 3/16	.0035	.005	.0065
3/16 to 1/4	.005	.0065	.0085
1/4 to 3/8	.0065	.0085	.0105
3/8 to 1/2	.0085	.0105	.0130
1/2 to 3/4	.0105	.0130	.0155
3/4 to 1	.0130	.0155	.0230
1 to 1 1/2	.0155	.0205	.0318
1 1/2 to 2	.0185	.0313	.0408
2 to 3	.030	.0430	.0528
3 to 4	.....	.0550	.0730
4 to 5	.....	.0725	.095
5 to 6	.....	.....	.125
6 to 7	.....	.....	.165
7 to 8	.....	.....	.210

As an example of actual variations in coil diameters to be expected in practice, the tolerances given by one spring manufacturer are listed in Table 7 (Ref. 9). It may be seen that these tolerances depend both on the spring index D/d and on the mean diameter D.

Effect of Modulus of Rigidity. An accurate calculation of the deflection of actual springs requires that the modulus of rigidity of the spring material be known with good accuracy. However, modulus values reported in the literature vary considerably for different materials. In particular, the effect of a decarburized layer only a few mils thick may reduce the effective modulus by several per cent. On the basis of available data a good average figure for modulus of rigidity for carbon and alloy steels is 11.5×10^6 psi. However, for hot-wound carbon-steel springs made from hot-rolled material in the larger sizes, some manufacturers recommend a modulus figure of 10.5×10^6 psi. Average values of the modulus for various spring materials are given in Table 8. However, it should be noted that in individual cases deviations of several per cent may occur from these values.

Table 8. Average Values for Modulus of Rigidity—Spring Materials

Material	Modulus of Rigidity, psi
Music wire under 0.015 diameter	12×10^6
Music wire over 0.015 diameter Carbon and chrome-vanadium steels	11.5×10^6
Hard-drawn stainless steel	10.5×10^6
Monel metal	9×10^6
Phosphor bronze	6×10^6

For springs operating at elevated temperature, the modulus is reduced. Test data indicate that for carbon, alloy, or stainless steels this reduction will be about 5% at 300 F and about 10% at 600 F (Ref. 1, p. 81).

Stress at Solid Compression. In the design of compression springs it is usually desirable to choose the coil pitch so that when the spring is compressed solid, no appreciable permanent set will occur. The reason for this is that in operation the spring may at times be compressed solid, and, if under these conditions it takes a set, the load at working deflections will be changed; hence the spring will no longer have its initial characteristics. Thus the stress at solid compression should not in general exceed certain limits.

Suggested corrected stresses at solid compression for various spring materials as given by Associated Spring Corp. (Ref. 15) are listed in Table 9. In the second column is given the stress at solid compression up to which it is not necessary to remove set, while in the last column is given the stress at solid compression which may be used after all set is removed by means of repeated compressions of the spring in the cold-setting operation.

Table 9. Suggested Corrected Stresses at Solid Compression—Helical Springs

VIBRATION AND SURGING OF HELICAL SPRINGS. When helical springs are subject to rapid alternation of load, vibration (or surging, as it is also called) of the coils may occur due to dynamical effects. Examples of such springs are valve springs for internal-combustion engines and recoil springs for guns. Particularly severe dynamical effects may occur in such cases when a harmonic in the motion of the spring end (or in the valve lift curve of valve springs) has a frequency which coincides with one of the natural frequencies of the spring (corresponding to one of the modes of vibration). For example, harmonics of very high order (up to the fifteenth or twentieth) may have to be considered in valve spring design. Usually the lowest natural frequency is of the most importance. For a spring compressed between parallel plates the first mode of vibration (corresponding to the lowest natural frequency) will consist of a motion of the middle part of the spring with the ends remaining stationary. The second mode of vibration (corresponding to a higher frequency) will have a node (or point of zero motion of the coils) in the middle of the spring, while maximum motion of the coils occurs at points one-fourth and three-fourths of the length distant from a given end of the spring.

Natural Frequencies. The lowest natural frequency f in cycles per second for a helical spring clamped between two parallel plates (Ref. 1, p. 232) is given by

$$f = \frac{d}{2\pi r^2 n}\sqrt{\frac{Gg}{32\gamma}} \text{ cycles per second} \tag{9}$$

where d = wire size, inches; r = mean coil radius, inches; G = modulus of rigidity, pounds per square inch; g = acceleration of gravity, inches per second^2 (g = 386 inches per second^2); γ = specific weight of material, pounds per inch^3; and n = number of active coils.

For usual steel springs having both ends clamped, where $G = 11.5 \times 10^6$ psi and $\gamma = 0.285$ lb per inch^3, the lowest natural frequency f becomes

$$f = \frac{3510d}{r^2 n} \text{ cycles per second} \tag{10}$$

Frequencies in the higher modes of vibration will be 2, 3, 4, etc., times this frequency.

For a spring with one end free and the other clamped, the lowest natural frequency would be equal to that of a similar spring twice as long but with both ends clamped. For such a spring eq. 10 may be used if the number of turns is taken as twice the actual number in the spring.

EXAMPLE 6. As an example of the use of these equations in calculating natural frequency, assume a steel spring with d = 0.3 in.; r = 1 in.; n = 6. Using eq. 10, the lowest natural frequency becomes

$$f = \frac{3510 \times 0.3}{(1)^2 \times 6} = 175 \text{ cycles per second}$$

In the second mode of vibration the spring frequency will be double this (or 350 cycles per second).

Methods of Reducing Surge or Vibration. To reduce stresses due to resonant vibrations in valve springs several methods are useful. The natural frequency of the spring should be made as high as possible so that resonance will occur only for the higher order harmonics (which are usually of lower amplitude). The cam contour may also be shaped so as to reduce the amplitudes of the harmonics which are of importance in the speed range within which the engine is to be used. In many cases it is possible by a change in the cam contour to reduce the magnitudes of the critical harmonics to low values within the speed ranges of importance. Reducing or varying the pitch of the coils near the ends of the spring will often result in an improvement. The reason for this is that if resonance occurs with one harmonic, the end coils will close up, thus changing the natural frequency of the spring and tending to throw it out of resonance. Friction dampers, consisting of a three-pronged device with the prongs pressing against the center coils of the spring, have also been used to damp out resonant oscillations.

2. HELICAL TENSION SPRINGS

In designing tension springs the weakening effect of the end coils should be considered. Unless special care is taken in the manufacture of such springs a fairly sharp curvature of the wire or bar at the point where the hook joins the body of the spring may occur.

Thus if a half-end turn of a tension spring is bent up sharply during manufacture, a sharp curvature at point A (Fig. 17) tends to result in a high concentration of stress at this point with the result that most failures of tension springs occur at such points. For this reason, and also because tension springs cannot usually be cold set without leaving excessive space between turns, a somewhat lower working stress (about 20 to 25% lower) is usually recommended as compared with those used in compression springs. The stress-concentration effect may be reduced (and the strength increased) by shaping the end turn so that the radius of curvature is as large as possible.

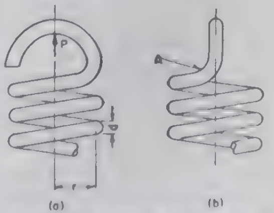

FIG. 17. Tension spring with sharp curvature at end loop

INITIAL TENSION. In cold-wound tension springs it is possible by partly overlapping the wire as it is fed to the coiling machine or mandrel to produce *initial tension*, i.e., a certain initial load must be applied to the spring before the coils start to separate. After separation of the coils begins, the spring rate or slope of the load-deflection diagram is the same as that which would be obtained for a spring with no initial tension. This effect is important in the operation of many mechanisms.

Values of initial tension load P_1 which can be obtained without difficulty in practice are given by the formula (Ref. 16):

$$P_1 = \frac{\pi S_s d^3}{16r} \tag{11}$$

where S_s = torsion stress due to initial tension, d = wire diameter, and r = mean coil radius.

Values of S_s depend on the spring index $2r/d$ and may be taken from Table 10.

Table 10. Torsional Stress Corresponding to Initial Tension

Spring Index, $2r/d$	Initial Tension Stress, psi
3	24,000
4	22,500
5	20,000
6	18,000
7	16,200
8	14,500
9	13,000
10	11,600
11	10,600
12	9,700
13	8,800
14	7,900
15	7,000

EXAMPLE 7. Assume a tension spring of 2-in. OD, $\frac{1}{4}$-in. wire diameter, and index $2r/d = 7$. When wound with initial tension, from Table 10 the stress due to this tension will be S_s = 16,200 psi. From eq. 11 the initial tension load becomes

$$P_1 = \frac{\pi(16{,}200)(0.25)^3}{16 \times (0.875)} = 57 \text{ lb}$$

By changes in the method of winding, values of initial tension greater than this may also be obtained but usually at extra expense.

TYPES OF SPRING ENDS. Usually the end turns of tension springs are made in the simple forms indicated in Fig. 18, which also shows some of the variations possible. Some of these designs may, however, result in a considerably greater stress in the spring than that calculated on the basis of an axial load. For example, if the loop is at the side, the moment arm of the load (on which the maximum torsion stress in the springs depends) is practically twice that which would exist if a purely axial load were applied to the same spring. This means a doubling of the stress.

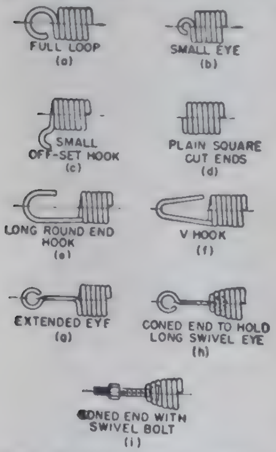

FIG. 18. Types of tension spring ends.

Sometimes in the actual loading of tension springs, even if the usual type of end loop is used, the line of action of the load may still be displaced by an appreciable amount from the axis of the spring. In this case a considerable increase in stress may also occur and should usually be considered.

Often tension springs are made with plain ends. Special fixtures called *spring ends* are attached to these as indicated in Fig. 19*a*. When using these, the spring is close wound and the ends of the spring are spread apart by screwing the spring into the holes. In this case an initial stress corresponding to the spreading apart of the turns near the ends is set up. This initial stress will correspond to a load equal to the initial tension in the spring plus the load corresponding to the distance the end coils are spread apart. A second type of spring end is shown in Fig. 19*b*. This is screwed into the ends of the spring coiled without end loops.

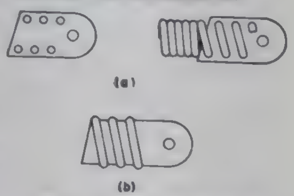

FIG. 19. Spring ends.

Designs shown in Fig. 18*h* and *i* will have relatively low stress in the end loops.

WORKING STRESSES FOR TENSION SPRINGS. An example of possible working stresses in tension springs for ordnance applications where space is restricted and only a limited life is required is shown in Fig. 20 for various materials (data from SAE Spring Committee, Ref. 4). In general, where more space is available and longer life is desired, stresses around 20 or 25% lower than these values should be used.

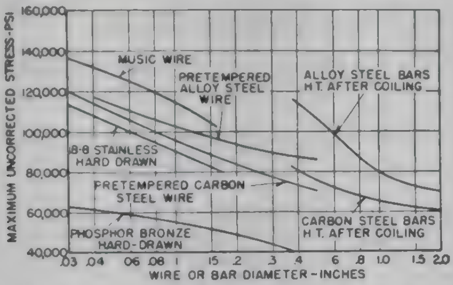

FIG. 20. Stresses for tension springs in ordnance applications where space is limited, and where only short life is required. (Data from *SAE Manual*, Ref. 4)

If fatigue is present, it is suggested that the design be carried out in the same manner as for compression springs (p. 11-07) using stresses about 20% lower.

3. SQUARE- OR RECTANGULAR-BAR SPRINGS

Helical tension or compression springs of rectangular bar section are sometimes used to provide a maximum amount of energy storage within a given space. Theoretically, a square-bar spring having the same material, bar size, and OD as a round-bar spring will be able to carry about 27% more load before complete yielding occurs over the cross section. This advantage is partially offset by the fact that it is difficult to obtain material in the square or rectangular section of equal quality to that in the round section. Also the stress distribution under elastic conditions is not as uniform in the square or rectangular section as it is in the round. This nonuniformity may be of importance where repeated loading is present.

SQUARE WIRE. Neglecting correction for curvature and direct shear, the uncorrected stress in a helical spring of square section is

$$S_s = \frac{4.8Pr}{a^3} \tag{12}$$

where P = load, a = side of square cross section, and r = mean coil radius.

Deflection δ of a square-bar helical spring is given by

$$\delta = \frac{44.6Pr^3n}{Ga^4} \tag{13}$$

where n = number of active coils and G = modulus of rigidity. This formula may be around 2 to 4% in error for indexes between three and four, but for most practical cases it is sufficiently accurate.

For square wire the *corrected* stress is found by multiplying the stress of eq. 12 by a factor K' (Ref. 3), where

$$K' = 1 + \frac{1.2}{c} + \frac{0.56}{c^2} + \frac{0.5}{c^3} \tag{14}$$

In this equation $c = 2r/a$ = spring index. This factor is slightly below the factor K for round wire (eq. 5).

In general when a square-wire spring is wound, as a consequence of plastic deformation during coiling, the section becomes trapezoidal as indicated in Fig. 21. In such cases an approximation may be had by taking an average value of a equal to

$$a = \frac{b_1 + b_2 + 2a_1}{4}$$

and taking the spring index equal to $2r/a_1$ for finding K'.

Table 5 and Figs. 11 and 12 which apply to round-wire helical springs may also be used for an approximate calculation of loads and deflections in square-wire springs at given uncorrected stresses. It is merely necessary to calculate the load and deflection at the given working stress in the corresponding round-wire spring, i.e., one having the same outside coil diameter and number of turns and a wire diameter equal to the average side of the square cross section. The loads thus found are multiplied by the factor 1.06 and the deflections by 0.738 to find those for the square-wire spring at the given stress.

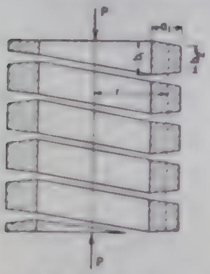

Fig. 21. Helical spring of square wire as actually coiled. The wire becomes somewhat trapezoidal due to the coiling operation.

RECTANGULAR-WIRE SPRINGS. The uncorrected stress in a spring of rectangular wire (Fig. 22) is

$$S_s = \frac{Pr(3a + 1.8b)}{a^2b^2} \tag{15}$$

where a = long side and b = short side of rectangle. This formula holds regardless of whether the spring is coiled flatwise as in Fig. 22 or lengthwise with the long side of the section parallel to the spring axis. However, the correction for curvature is different in the two cases.

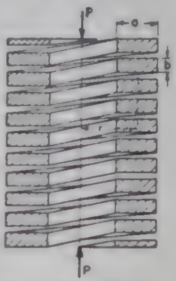

Fig. 22. Helical spring of rectangular wire coiled flatwise.

To calculate corrected stress S_s' in rectangular-bar springs, the chart of Fig. 23 may be used (Ref. 17). This gives

$$S_s' = \beta \frac{Pr}{ab\sqrt{ab}} \tag{16}$$

Note that in this case a and b are sides perpendicular and parallel respectively to the spring axis (Fig. 23), and β is a factor depending on the ratio a/b or b/a and on the spring index $2r/a$. (Note that in this case b always represents the side parallel to the spring axis.)

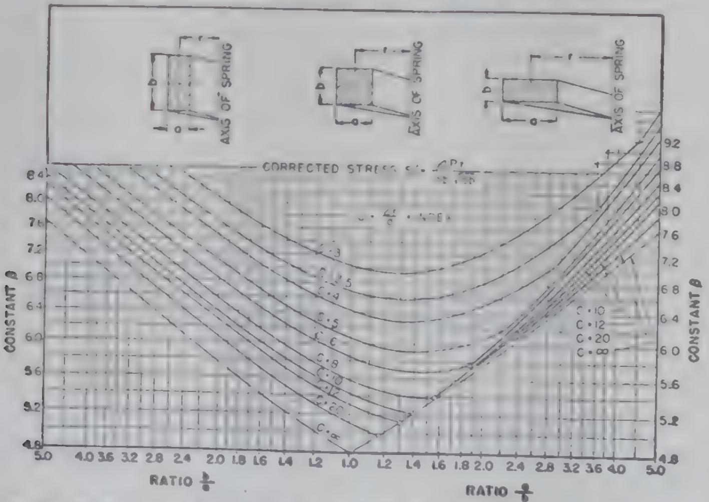

Fig. 23. Curves for finding stress factor β for rectangular bar springs. (Data from charts by Liesecke, Ref. 17, p. 425)

Example 8. Spring coiled flatwise as in Fig. 22. Dimensions are: $a = 1/2$ in., $b = 1/4$ in., $a/b = 2$, $r = 1.5$, $c = 2r/a = 6$, $P = 300$ lb. From Fig. 23 for $a/b = 2$, $c = 6$, $\beta = 5.88$. Corrected stress S_s' is (from eq. 16)

$$S_s' = \beta \frac{Pr}{ab\sqrt{ab}} = \frac{5.88(300)1.5}{(0.25)(0.5)\sqrt{0.125}} = 60{,}000 \text{ psi}$$

To calculate deflections in rectangular-bar springs having large indexes (say greater than 8), the following formula, based on torsion of a straight bar of rectangular section, will yield results accurate to within a few percent where the pitch angle is not large:

$$\delta = \frac{19.6Pr^3n}{Gb^3(a - 0.56b)} \tag{17}$$

In this formula a represents the long side and b the short side of the cross section (Fig. 22).

For both small and large indexes, the deflection of a rectangular-bar spring may be calculated by using the chart of Fig. 24 (Ref. 17). Deflection is

$$\delta = \frac{8\gamma P r^3 n}{a^2 b^2 G} \tag{18}$$

where the constant γ depends on the ratio a/b or b/a and may be taken from Fig. 24.

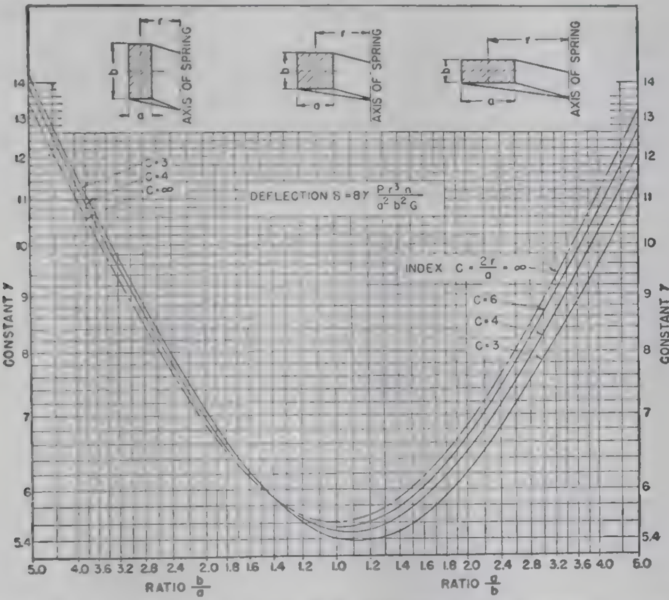

FIG. 24. Curves for finding deflection factor γ for rectangular bar springs. (Data from charts by Liesecke, Ref. 17, p. 892)

Here b is the side parallel to the spring axis, and a the side perpendicular thereto. If the spring is coiled flatwise, the ratio a/b is taken; if it is coiled edgewise, a ratio b/a is taken. (See sketches on Fig. 24.)

EXAMPLE 9. A spring is coiled flatwise with $a = 1/2$ in., $b = 1/4$ in., $r = 1.5$ in., $P = 300$ lb, number of active turns $n = 5$, and $G = 11.5 \times 10^6$ lb per sq in. (steel). From Fig. 24 the constant $\gamma = 6.7$ for $a/b = 2$, $2r/a = 6$. From eq. 18

$$\delta = \frac{8\gamma P r^3 n}{a^2 b^2 G} = \frac{6.7 \times 8 \times 300 \times 3.37 \times 5}{0.25 \times 0.0625 \times 11.5 \times 10^6} = 1.51 \text{ in.}$$

4. HELICAL TORSION SPRINGS

Helical torsion springs have essentially the same shape as helical compression or tension springs, except that the ends are formed in such a way that the spring may be subject to torque about the coil axis instead of an axial load. Because of the mode of stressing of such springs the primary stress is *flexural*, in contrast to the helical compression or tension spring where the primary stress is *torsional*. Typical shapes of ends for torsion springs are shown in Fig. 25. They are made primarily for the purpose of transmitting external torque to the spring. Examples of torsion spring applications include door-hinge springs, springs for starters in automobiles, and springs for brush holders in electric motors.

A typical method of loading a torsion spring is illustrated in Fig. 26, where the spring is wound around a rod, one end of it being fastened to the rod while the other end has a straight portion projecting radially. If the spring is loaded by a force P at a radius R from the axis so as to wind the spring, the moment tending to twist the spring will be PR as indicated. Because of friction between the spring and guide the actual moment may decrease along the spring so that an exact calculation becomes rather involved.

In most cases it is advisable to load torsion springs in such a way that the spring tends to wind up as the load is applied. The reason for this is that the residual stresses set up as a consequence of cold winding are in such a direction as to subtract from the peak stress due to the loading, provided the load is in a direction tending to wind up the spring. If the direction of loading is such as to unwind the spring, a low-temperature heat treatment to remove such stresses is advisable.

Another reason for loading the spring in this manner is (see Fig. 26 for a load tending to wind up the spring) that the reaction will be against the arbor, and the peak bending moment in the spring will be PR. However, if the load is in the opposite direction to that shown, the peak moment on the wire will be $P(R + r)$, which may be considerably greater, r being the mean radius of the coil.

Often, if the ends of the spring are clamped or if special ends are used, some stress concentration may be expected near the ends. These stress concentrations should be carefully considered, particularly if the spring is subject to repeated loading.

Because a torsion spring (for usual applications) tends to wind up with load, its diameter decreases. In design it is important that sufficient clearance be allowed between the arbor or rod about which the spring is wound and the inner diameter of the spring. If this is not done, the spring may bind or wrap around the arbor and high stresses will be set up.

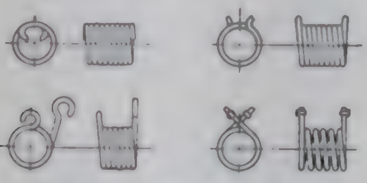

Fig. 25. Torsion spring ends.

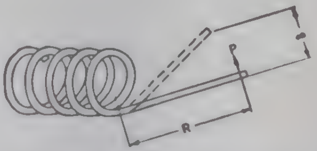

Fig. 26. Typical method of loading a torsion spring.

The clearance necessary may be estimated from the calculated deflection of the ends of the spring as given by eq. 21. Thus if the spring end deflects 90 degrees or one-fourth turn and the spring has 8 turns, the diameter will change in the ratio of $^1/_4$ to 8 or by about 3%, which should be allowed for in design. Likewise if the spring fits inside a tube and is loaded so as to unwind, sufficient clearance must be allowed between the outside diameter of the spring and the inside diameter of the tube.

Where torsion springs are relatively long, there is always the possibility of torsional buckling if the torque exceeds a certain value. This may be avoided by providing such springs with guides (such as rods or tubes). By properly clamping the ends or by applying an initial tension load, buckling may sometimes be avoided, and guides may not be required.

Usually, for manufacturing reasons, torsion springs are made of round wire. However, where maximum energy storage is required in a given space the use of square or rectangular wire may be advisable since the material is stressed more efficiently in such sections. Also for a given spring index, more material may be provided within a given outside diameter in the case of rectangular wire; this further increases the amount of energy which may be stored in a given space.

DESIGN FORMULAS FOR TORSION SPRINGS. Stresses and Deflections. Uncorrected stress for *circular* wire is

$$S = \frac{32M}{\pi d^3} \tag{19}$$

where M = bending moment and d = wire diameter.

Since this spring is essentially a curved bar, there will be a stress augment due to bar curvature which may be calculated from curved bar theory (Ref. 1). The corrected stress S' then becomes

$$S' = K_1 \frac{32M}{\pi d^3} \tag{20}$$

where K_1 depends on the spring index $2r/d$ and may be taken from the curve of Fig. 27.

Angular deflection ϕ in radians due to a given moment M is

$$\phi = \frac{128Mrn}{Ed^4} \tag{21}$$

where r = mean coil radius, n = number of active coils, and E = modulus of elasticity.

For a load P at the end of the spring as in Fig. 26, neglecting friction, the deflection δ along the arc will be

$$\delta = \frac{128PR^2rn}{Ed^4} \tag{22}$$

where R = lever arm of load P.

For *rectangular-bar* torsion springs, the corresponding formulas are:

$$\text{Uncorrected stress: } S = \frac{6M}{bh^2} \tag{23}$$

where b = width, and h = depth of section, and

$$\text{Corrected stress: } S' = K_2\left(\frac{6M}{bh^2}\right) \tag{24}$$

where K_2 depends on the ratio $2r/h$ (Fig. 27).

Angular deflection ϕ in radians is

$$\phi = \frac{24\pi Mrn}{Ebh^3} \tag{25}$$

Deflection δ along arc due to load P (Fig. 26) is

$$\delta = \frac{24\pi PR^2rn}{Ebh^3} \tag{26}$$

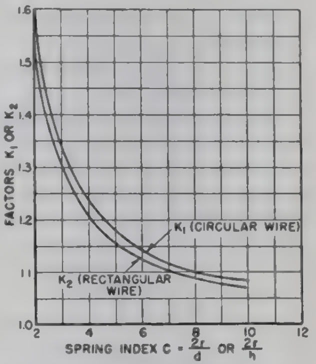

FIG. 27. Stress concentration factors K_1 and K_2 for torsion springs of circular and rectangular wire.

EXAMPLE 10. A brush-holder spring for small motors is loaded as indicated in Fig. 26. Dimensions are: load arm $R = 7/8$ in.; mean coil radius $r = 3/16$ in.; wire size $d = 0.04$ in.; spring index $c = 2r/d = 9.4$. The load P at the end of arm is 1 1/4 lb. From Fig. 27 the factor K_1 for $c = 9.4$ is 1.08. Using eq. 20, the corrected stress is (taking $M = PR$)

$$S' = K_1\frac{32M}{\pi d^3} = \frac{1.08 \times 32 \times 1.25 \times 0.875}{\pi \times (0.04)^3} = 188{,}000 \text{ psi}$$

If there are ten active turns, from eq. 21 the deflection in radians is (for $E = 30 \times 10^6$ psi)

$$\phi = \frac{128Mrn}{Ed^4} = \frac{128 \times 1.25 \times 0.875 \times 0.187 \times 10}{30 \times 10^6 \times (0.04)^4} = 3.4 \text{ radians}$$

This corresponds to a deflection of slightly more than 180 degrees.

Working Stresses. Maximum design stresses for torsion springs of different wire sizes and materials for average service conditions suggested by American Steel and Wire Company are given in Table 11 (Ref. 9). These conditions are defined as noncorrosive atmosphere, temperatures not exceeding 150 F, and relatively slowly varying or static loads.

Where the spring is subject to repeated or fatigue stresses through a considerable range, in general it will be necessary to use much lower working stresses than those suggested in Table 11. This is also true if the spring is subject to high temperatures or corrosion conditions. In such cases, consultation with the spring manufacturer is advisable.

Table 11. Recommended Maximum Design Stresses *—Helical Torsion Springs

(For average service conditions)

	Kind of Wire (Plain Carbon Steels)		
Diameter d	Hard-drawn	Tempered	Music
.004–.009	....	....	280,000
.010–.020	....	....	270,000
.021–.040	160,000	....	240,000
.041–.060	160,000	180,000	220,000
.061–.080	160,000	180,000	210,000
.081–.100	140,000	180,000	200,000
.101–.150	130,000	165,000	185,000
.151–.225	110,000	145,000	165,000
.226–.400	....	135,000	
.401–.625	....	125,000

Monel metal		60,000	
Brass		30,000	

* Computed by taking curvature effects into account.

5. SPIRAL SPRINGS

Spiral springs consist essentially of flat strip wound to form a spiral shape (Fig. 28). Usually the inner end is clamped to an arbor while the outer end may be either pinned or clamped. Common applications are springs for clocks and watches and motor brush-holder springs. If the individual turns of the spring do not come in contact, as in the spring for the balance wheel of a watch, the analysis of such springs may be carried out with a considerable degree of accuracy. However, when the spring is wound up tightly (as in a clock spring) the analysis is different. These cases will be treated separately.

SPRING WITH LARGE NUMBER OF TURNS. Clamped Outer End. It is assumed that the outer end of the spring is clamped or built in as indicated in Fig. 28, and that the spring has several turns or more which are, however, separated sufficiently so that adjacent turns do not come in contact during operation. The inner end of the spring is assumed to be fastened to an arbor which pivots about point O and is acted on by moment M_0. Under these assumptions the angular deflection ϕ of the arbor with respect to the clamped end is given by

$$\phi = \frac{M_0 l}{EI} \text{ radians} \tag{27}$$

where l = length of spiral, E = modulus of elasticity, $I = bh^3/12$ moment of inertia of section. To obtain the degrees of rotation, eq. 27 must be multiplied by 57.3.

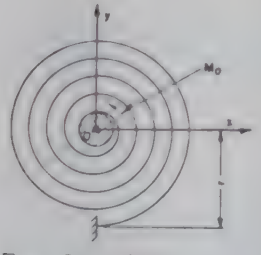

Fig. 28. Spiral spring with large number of turns (clamped outer end).

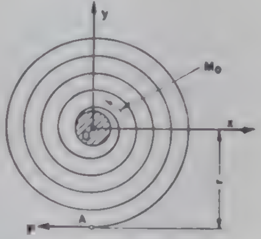

Fig. 29. Spiral spring with large number of turns (pinned outer end).

Since the moment is constant along the length, the stress for a spiral spring with the end conditions of Fig. 28 will be given by

$$S = \frac{6M_0}{bh^2} \tag{28}$$

where b = width of spring and t = thickness. Usually, however, there is some stress concentration at the clamped ends of the spring. Where fatigue loading is present this should be taken into account (see p. 11-38).

For a spring with a small number of turns, say less than two, the angular deflection ϕ will in general be around 3 to 15% less than that given by eq. 27. The peak stress will also be considerably greater than the value given by eq. 28 if the number of turns is less than about 3. For example, for 1 turn the ratio of the peak stress to the value given by eq. 28 varies from 1.35 to about 1.6, depending on the ratio of inside to outside diameter of the wound portion; for three turns this ratio varies from 1.12 to 1.19 (Ref. 18). These values assume a ratio of inside to outside diameter of the wound portion varying between 0.4 and 0.6.

Pinned Outer End. Frequently in practice the outer end A (Fig. 29) of the spiral spring is hinged instead of being clamped. In this case the external moment M_0 may be taken as Pr, and an analysis shows a value for angular deflection about 25% greater than for the clamped-end condition (Fig. 28) for the same applied moment and assuming a large number of turns.

The maximum stress S in this case is

$$S = \frac{12M_0}{bh^2} \tag{29}$$

Although this stress is twice that for a spring with a clamped outer edge (eq. 28) it occurs at a point where there is no stress concentration.

Example 11. A steel spiral spring having a pinned end (Fig. 29) is subject to a torque M_0 equal to 25 in.-lb. The outer diameter is 2 in., the strip section is $^1/_2$ by 0.060 in., and the total length of the spiral is 15 in. Required: the stress and the deflection.

$$I = \frac{bh^3}{12} = 9.0 \times 10^{-6}$$

$$E = 30 \times 10^6 \text{ psi}$$

From eq. 27, for a clamped end, $\phi = \dfrac{M_0 l}{EI} = \dfrac{25 \times 15}{30 \times 10^6 \times 9 \times 10^{-6}} = 1.39$ radians. For a pinned end, this will be 25% greater, or $1.25 \times 1.39 = 1.74$ radians. Since 1 radian = 57.3 degrees, this means a deflection at this torque equal to $57.3 \times 1.74 = 100$ degrees.

From eq. 29 the maximum stress is

$$S = \frac{12M_0}{bh^2} = \frac{12 \times 25}{0.5 \times (0.06)^2} = 167{,}000 \text{ psi}$$

The nominal stress at the clamped end O where stress concentration occurs will be but half of this, or 84,000 psi.

Working Stresses. Working stresses in spiral springs may run as high as 175,000 psi for $^1/_8$-in. thick steel strip to 240,000 psi for $^1/_{32}$-in. strip, in applications where fatigue conditions are not a factor. For example, an ordinary clock spring during its life may be subject to less than 5000 cycles, and hence may be stressed much higher than if millions of cycles were involved. When fatigue conditions are present (as, for example, in the spiral spring for the balance wheel of a watch) the stress range should be kept well below the endurance range of the material, stress concentration conditions at the clamped edges being considered (see p. 11-38).

SPIRAL SPRINGS WITH LARGE DEFLECTIONS. Coils in Contact. The previous discussion of spiral springs has been based on the assumption that individual coils do not touch each other. This condition, however, does not apply in many cases, as for example in the power spring of a phonograph. In such cases the spring is usually placed inside a hollow case as indicated in Fig. 30. Here the spring is shown wound up on the arbor.

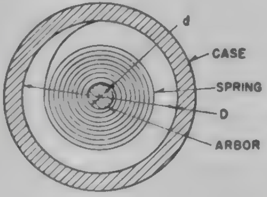

Fig. 30. Spiral spring wound on arbor.

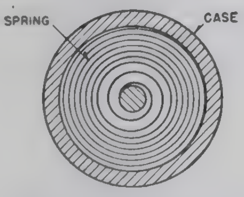

Fig. 31. Spiral spring unwound and resting against case.

When the spring is unwound it rests against the inside of the case as indicated in Fig. 31.

To find the total number of turns N delivered by the spring in unwinding from the wound-up position of Fig. 30 to the unwound position of Fig. 31, the following expression may be used (Ref. 19):

$$N = \frac{K}{2h}\left(\sqrt{\frac{4}{\pi} lh + d^2} + \sqrt{D^2 - \frac{4}{\pi} lh} - D - d\right) \tag{30}$$

where l = total length of spring, h = strip thickness, and d, D are dimensions given in Fig. 30. The factor K depends on the ratio m given by

$$m = \frac{\pi}{4lh}(D^2 - d^2) \tag{31}$$

Values of K for various values of m are given in Table 12.

Table 12

m	5	4	3	2	1.5
K	0.672	0.702	0.739	0.796	0.85

In practice, to avoid excessive stress, the arbor diameter is usually made about 15 to 25 times the strip thickness.

Example 12. A spiral spring is made of 0.015 × 3/4 in. strip steel, 100 in. long. Arbor diameter is 3/8 in., and inner diameter of the case is 2 1/4 in. The problem is to find the number of turns delivered from the solid to the free condition. Thus $h = 0.015$, $l = 100$, $D = 2.25$, and $d = 0.375$ in.

From eq. 31,

$$m = \frac{\pi}{4(0.015)(100)}\left(\sqrt{2.25^2 - 0.375^2}\right) = 2.58$$

From Table 12, by interpolation, for $m = 2.58$, $K = 0.76$.

If the given values of K, l, D, and d are used in eq. 30, $N = 14.9$ turns which will be delivered by the spring in unwinding.

6. FLAT SPRINGS

SIMPLE CANTILEVER SPRING. Springs made from flat strip or bar stock are usually called flat springs even though they may be formed into more or less complicated shapes. Frequently, however, such springs may be considered as simple cantilevers (Fig. 32).

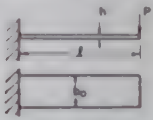

Fig. 32. Simple cantilever spring.

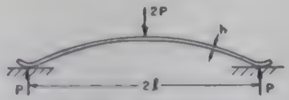

Fig. 33. Bowed strip.

Thus the spring shown in Fig. 33, which consists of a single bowed strip, may be considered essentially as a cantilever spring of length l loaded by a force P.

The formula for deflection of a simple cantilever spring is

$$\delta = \frac{4Pl^3}{Eb_0h^3} \tag{32}$$

where l = length (Fig. 32), b_0 = width, h = thickness, and E = modulus of elasticity of the material, pounds per square inch.

Where the thickness h is small compared to the width b_0, as in most practical cases, somewhat more accuracy, in general, will be obtained by multiplying the deflection figured by the simple cantilever formula by a factor 0.91. This factor takes into account the stiffening effect which occurs because lateral expansion or contraction of elements near the surface of the strip is prevented.

The maximum nominal stress is given by

$$S = \frac{6Pl}{b_0h^2} \tag{33}$$

Note that, if repeated loading is present, this stress may be augmented by stress concentration effects (p. 11-29).

TRAPEZOIDAL PROFILE SPRING. Somewhat more efficient use of material is obtained from the cantilever spring of trapezoidal profile (Fig. 34). Also leaf springs of the usual shape may, for practical purposes of analysis, be frequently considered as cantilever springs of trapezoidal profile as shown in Fig. 35. For a given load P the maximum stress is again given by eq. 33; in this case b_0 is the width at the built-in end.

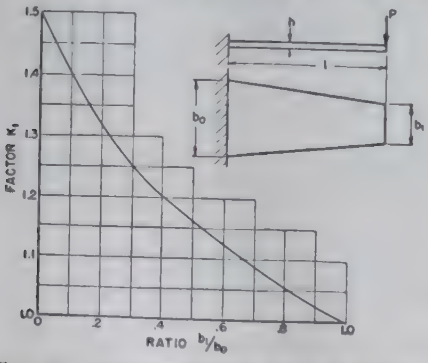

Fig. 34. Curve for finding factor K_1 (trapezoidal profile spring).

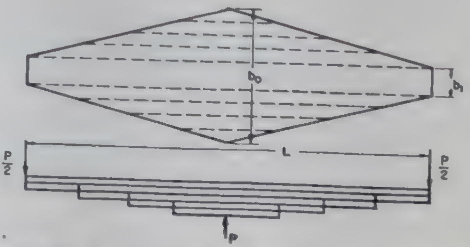

Fig. 35. Semi-elliptic leaf spring reduced to two trapezoidal cantilever springs.

However, analysis based on ordinary beam theory shows that for a trapezoidal profile spring, the deflection is:

$$\delta = K_1 \left(\frac{4Pl^3}{Eb_0h^3} \right) \tag{34}$$

where

$$K_1 = \frac{3}{\left(1 - \dfrac{b_1}{b_0}\right)^3} \left[\frac{1}{2} - 2\frac{b_1}{b_0} + \left(\frac{b_1}{b_0}\right)^2 \left(\frac{3}{2} - \log_e \frac{b_1}{b_0} \right) \right]$$

and b_1 = width at loaded end (Fig. 34). The factor K_1 may be taken from the curve of Fig. 34 for various values of b_1/b_0. It is thus seen that the deflection of a trapezoidal profile spring is equal to that of a rectangular profile spring multiplied by the factor K_1. Theoretically the most efficient spring is obtained where $b_1/b_0 = 0$ since, other things being equal, this value gives the maximum deflection for a given value of load. Practical considerations, however, usually dictate a value of b_1/b_0 greater than zero. When b_0 is very large compared to the thickness, the deflection given by eq. 34 should be multiplied by a factor 0.91, as explained previously.

STRESS-CONCENTRATION EFFECTS IN FLAT SPRINGS. (a) Sharp Bends. Frequently flat springs are formed with sharp bends (Fig. 36) which produce stress-concentration effects. To obtain the corrected stress in such cases the nominal stress calculated from eq. 33 must be multiplied by a stress-concentration factor K_2, which depends on the ratio $2r/h$ and may be taken from the curve marked K_2 in Fig. 27. Where fatigue loading is involved, it is advisable to calculate the stress *range* using the factor K_2; for static or infrequently repeated loading, K_2 may be assumed as unity, i.e., the uncorrected stress may be used. In general, sharp bends should be avoided as far as possible not only to reduce stress concentration but also for manufacturing reasons.

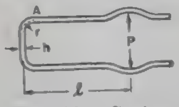

FIG. 36. Spring clip. Stress concentration is present due to sharp curvature of bend at *A*.

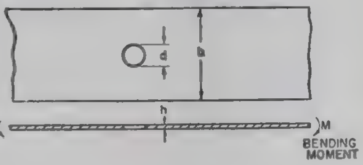

FIG. 37. Flat spring with hole large in diameter compared to thickness.

(b) Holes or Notches. A hole in a flat strip (Fig. 37) will result in a theoretical stress-concentration factor K_t equal to 1.85 if the hole diameter is large compared to the thickness h but small compared to the width b, i.e., if h/d and d/b are small compared to unity. Thus in this case the corrected stress would be $1.85[6M/(b - d)h^2]$, where M = applied bending moment. Where $h/d = 1/2$, the factor approximates 2; and where $h/d = 1$, $K_t = 2.25$, d/b being assumed small in both cases (Ref. 20). For very small d/h and d/b a theoretical value of K_t equal to 3 is obtained. These values are reduced somewhat if the hole diameter becomes an appreciable fraction of the width (Ref. 1, p. 300).

For semicircular notches of diameter d which are small compared to the width of the strip, values of K_t may be taken approximately the same as those for holes of the same diameter, and assuming the same ratios d/h.

Where fatigue loading is present it is advisable to use K_t in figuring the stress range.

WORKING STRESSES. For static loads or loads infrequently repeated, working stresses for flat springs made of 0.70 to 0.80 carbon steel (45 to 48 Rockwell C) may run as high as 180,000 psi for 0.125-in. thick strip to 240,000 psi for 0.025-in. thick strip (Ref. 5, p. 76). Where fatigue or repeated loading is present, much lower stresses than these should generally be used, and the corrected stress range should be kept well below the endurance range of the material.

7. LEAF SPRINGS

Sketches of a typical semi-elliptic leaf spring and of some typical ends and center clamps are shown in Figs. 38, 39, and 40. Rebound and alignment clips are illustrated in Fig. 41.

SYMMETRIC SEMI-ELLIPTIC LEAF SPRING. A semi-elliptic leaf spring of length L, loaded centrally by a force P (Fig. 42*a*), may as an approximation be considered as a trapezoidal cantilever spring (Fig. 35). Thus if there are n leaves (total) of width b, and

FIG. 41. Rebound clips.

n_1 leaves of length L, then $b_0 = nb$ and $b_1 = n_1 b$. The ratio b_1/b_0 will be n_1/n, and the curve of Fig. 34 may be used to find K_1. In this case the deflection δ at load P is

$$\delta = K_1 \frac{PL^3}{4Enbh^3} \tag{35}$$

where E = modulus of elasticity and h = thickness of leaves (assumed uniform).

Spring rate in pounds per inch is

$$\frac{P}{\delta} = \frac{4Enbh^3}{K_1 L^3} \tag{36}$$

If there is only one main leaf (Fig. 42*a*), the spring may frequently be considered approximately as a beam of uniform strength, $K_1 = 1.5$. In this case the spring rate in pounds per inch is

$$\frac{P}{\delta} = \frac{8Enbh^3}{3L^3} \tag{37}$$

Maximum stress in both cases is

$$S = \frac{3PL}{2nbh^2} \tag{38}$$

In practical springs where a center clamp is used, the length L in eqs. 35 to 38 is to be taken as the total length minus that of the center clamp.

UNSYMMETRIC SEMI-ELLIPTIC LEAF SPRING. For a leaf spring loaded unsymmetrically (Fig. 42*b*), all leaves being of equal thickness, approximate formulas for spring rate and stress, based on the assumption of a beam of uniform strength, are (Ref. 21)

$$\text{Rate } \frac{P}{\delta} = \frac{Ebnh^3L}{6l_1^2l_2^2} \tag{39}$$

$$\text{Stress } S = \frac{6Pl_1l_2}{Lnbh^2} \tag{40}$$

CANTILEVER SPRING (Fig. 42*c*), having n leaves, l being the length of the longest leaf, assuming a beam of uniform strength.

$$\text{Rate } \frac{P}{\delta} = \frac{Ebnh^3}{6l^3} \tag{41}$$

$$\text{Stress } S = \frac{6Pl}{nbh^2} \tag{42}$$

Equations 37 to 42, although based on the assumption that the spring may be considered as a beam of uniform strength (triangular profile), are frequently used in practical design even where these conditions are not strictly fulfilled. Effects which may cause deviations from the ideal conditions assumed are use of leaves of different thicknesses, use of more than one main leaf, interleaf friction, effects of spring shackles which result in angular loading at the ends. These effects may result in rather large deviations from the values calculated from the formulas (eqs. 37 to 42). For a further discussion, see Ref. 21.

WORKING STRESSES. Design stresses suggested by the SAE Spring Committee for automotive and railroad springs are given in Fig. 43 (Ref. 21). In calculating these stresses, eqs. 37 to 42 may be used, assuming that all leaves have equal thickness and free curvature. If the design is based on the static loading condition, as is frequently done, the design stress increases as the static deflection increases (lower curves of Fig. 43). Where possible, however, the design should be based on the maximum stress which occurs under conditions of maximum deflection, a value of 130,000 psi being suggested for carbon steel and 140,000 psi for alloy steel.

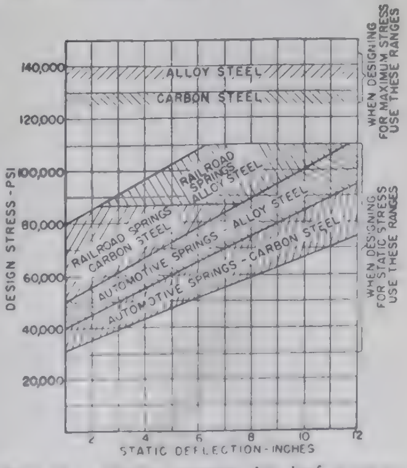

Fig. 43. Design stresses for leaf springs (SAE Spring Committee, Ref. 21)

Use of these stresses in general will result in a life of about 100,000 full-load cycles of stress (assuming that the springs have been shot-peened and cold-set). Also, a set of

3 to 5% of full-load deflection may be expected in service at these stresses. Where the spring operates under conditions of appreciable negative loading in rebound (i.e., when the stress may be reversed in direction) lower stresses than those of Fig. 43 must be used. Also, where other stresses than those due to vertical loading (such as wind-up torque stresses) are present, they must be considered in calculating maximum stress, or lower stresses must be used if the design is based on the static loading condition.

MATERIALS commonly used for leaf springs include SAE 1095, 4063, 5150, 6150, and 9260. In general, alloy steels are used for automotive springs and carbon steels are used for railway springs. Heat treatments giving Brinell hardnesses 415 to 460 will usually yield satisfactory results for spring steels. Also, shot-peening and cold-setting operations are desirable for satisfactory life in service.

8. INITIALLY CONED (BELLEVILLE) SPRINGS

The Belleville spring consists essentially of a coned or dished disk having a diametral cross section as shown in Fig. 44, the load being applied in the direction indicated by the arrow. On loading, the disk tends to flatten out, spring action being thus obtained. Changes in load-deflection characteristics obtained by varying the ratio h/t between cone height (or dish) and thickness are shown in Fig. 45. For ratios h/t around 0.5 the curve approximates a straight line, whereas for h/t equal to 1.5, the load is nearly constant (within a few percent) over a considerable range of deflection. For this reason springs having ratios approximating this value are frequently called *constant-load* or *zero-rate* springs.

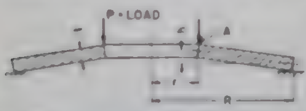

FIG. 44. Belleville spring.

Belleville springs may be used singly, stacked in parallel as shown in Fig. 46*a*, or stacked in series as shown in Fig. 46*b*. By stacking in parallel, load capacity is increased in proportion to number of disks; in addition, damping is obtained by friction between disks. By stacking in series the deflection for a given load is increased in proportion. Obviously with this latter arrangement deflections greater than the cone height cannot be obtained unless spacers are used. Belleville springs have high capacity and a relatively small space requirement in direction of load application, but this is obtained at the expense of a relatively nonuniform stress distribution across the section. Where a stack of springs is used, guides are usually necessary to avoid lateral buckling.

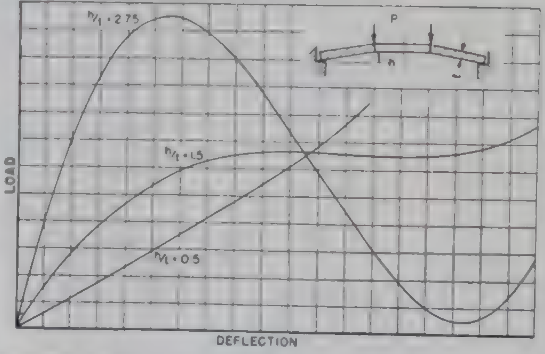

FIG. 45. Shapes of load-deflection diagrams obtained by varying ratio h/t.

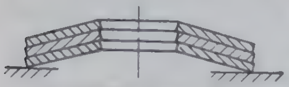
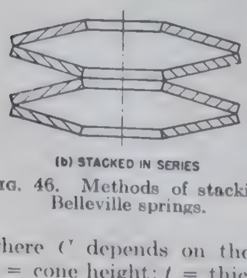
Where springs are stacked in series (Fig. 46*b*) ratios between cone height and thickness greater than 1.3 should not in general be used, since instability and an irregular load-deflection characteristic may result. A ratio of outside to inside diameter between 1.5 and 2.5 will usually prove most desirable in practice.



(a) STACKED IN PARALLEL



(b) STACKED IN SERIES

FIG. 46. Methods of stacking Belleville springs.

FORMULAS. The following approximate formulas for calculating stress and deflections in Belleville springs are based on the assumption that radial cross sections of the spring do not distort during deflection (Ref. 22). The results are in approximate agreement with available test data. However, high accuracy should not be expected since frictional and other effects not taken into account by these formulas can result in appreciable deviation between test and calculated results.

Load and Deflections. Load P at deflection δ is

$$P = \frac{1.1E\delta C}{R^2}\left[(h-\delta)\left(h-\frac{\delta}{2}\right)t + t^3\right] \tag{43}$$

where C depends on the ratio R/r (Fig. 47); R = outside radius; r = inside radius; h = cone height; t = thickness (Fig. 44); and E = modulus of elasticity of material.

This formula may be simplified (Ref. 1, p. 249) to the following:

$$P = \frac{CC_1Et^4}{R^2} \tag{44}$$

where C_1 is a load factor which depends on the ratios δ/t and h/t, given in the chart of Fig. 48.

It should be noted that the shapes of the curves for C_1 also represent the shapes of the load-deflection diagrams for the various ratios h/t. Where h/t is in the neighborhood of 1.4 to 1.6, approximately constant load results over a rather wide range of deflection. Theoretical load P_1 required to flatten spring is obtained from eq. 43, taking $\delta = h$. This gives

$$P_1 = \frac{1.1ECht^3}{R^2} \tag{45}$$

If the spring is tested against a flat plate, actual loads will be higher than P_1 because of the tendency of the spring to stiffen up near the flattened position.

Stress formulas are (Ref. 22) outlined below.

Maximum compression stress S_c at upper inner edge A (Fig. 44) at deflection δ is

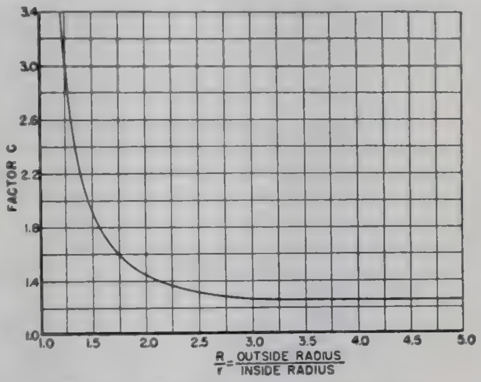


FIG. 47. Factor C, for Belleville springs.

$$S_c = \frac{-1.1E\delta C}{R^2}\left[C_2\left(h - \frac{\delta}{2}\right) + C_3t\right] \tag{46}$$

(Note that in general this will be the maximum stress in the spring provided δ is less than $2h$.) The factors C_2 and C_3 depend on the ratio R/r and may be taken from the curve of Fig. 49.

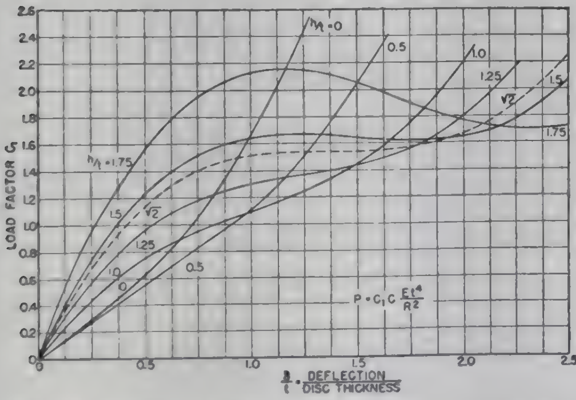

FIG. 48. Curves for determining load factor C_1, for Belleville springs.

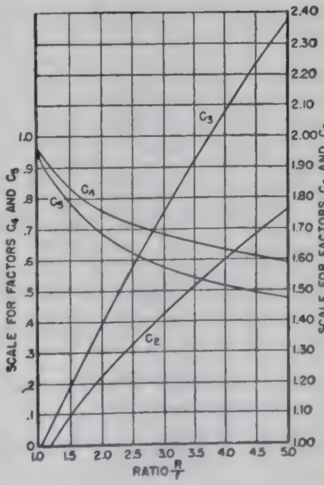

FIG. 49. Curves for finding C_2, C_3, C_4, and C_5, for Belleville springs.

Stress S_{t1} (normally tension) at lower inner edge of the spring is

$$S_{t1} = \frac{1.1E\delta C}{R^2}\left[-C_2\left(h - \frac{\delta}{2}\right) + C_3t\right] \tag{47}$$

Tension stress S_{t2} at lower outer edge of the spring is

$$S_{t2} = \frac{1.1E\delta C}{R^2}\left[C_4\left(h - \frac{\delta}{2}\right) + C_5t\right] \tag{48}$$

where C_4 and C_5 may be taken from the curve of Fig. 49. Since fatigue fractures frequently start at one of the lower edges, depending on the ratio h/t, either of the stresses S_{t1} or S_{t2} may be critical even though numerically smaller than the compression stress S_c.

In all cases in eqs. 46 to 48 a negative sign indicates compression and a positive sign tension.

It should be noted that if $\delta > 2h$, i.e., for deflections over twice the cone height, the stress at the lower inner edge S_{ii} (eq. 47) will become numerically larger than S_c.

Equation 46 for calculating S_c may be simplified to the following:

$$S_c = \frac{KEt^2}{R^2} \tag{49}$$

In this K is a stress factor depending on the ratios R/r, h/t, and δ/t, which may be taken from the lower group of curves of Fig. 50 for $R/r = 1.5$ and from those of Fig. 51 for R/r between 2 and 2.5. The negative value of K in these curves signifies a compression stress.

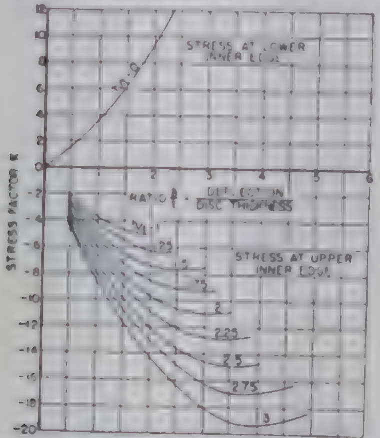

FIG. 50. Curves for determining stress factor K for Belleville springs (R/r = 1.5).

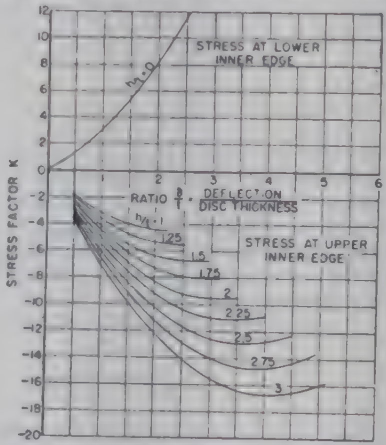

FIG. 51. Curves for determining stress factor K for Belleville springs (R/r = 2 to 2.5).

For a flat plate where $h/t = 0$, the upper curve of Fig. 50 may be used for $R/r = 1.5$ and that of Fig. 51 for $R/r = 2.0$ to 2.5. In this case, using K in eq. 49, the value of the tension stress at the lower inner edge is obtained.

It should be noted that there will usually be a small error involved in using the charts of Figs. 50 and 51, particularly for small values of h/t and δ/t. If greater accuracy is desired eq. 46 should be used.

Formulas for Small h/t Ratios. Where the ratio h/t between cone height and thickness is small (say less than about 0.5), the formulas for stress and deflection may be taken from flat plate theory to simplify the results. It is also assumed that δ/t is less than about 0.5. In such cases approximate deflection and stress are given by

$$\delta = K_1 \frac{PR^2}{Et^3} \tag{50}$$

$$S = K_2 \frac{P}{t^2} \tag{51}$$

In these K_1 and K_2 are factors depending on R/r and may be taken from Table 13.

Table 13. Factors K_1 and K_2 for Calculating Belleville Springs

(h/t and δ/t less than 0.5)

R/r	1.25	1.5	2	3	4
K_1	0.341	0.519	0.672	0.734	0.724
K_2	1.10	1.26	1.48	1.88	2.17

Nominal Stress across Diametral Section. Assuming that the spring is approximately flat when loaded, as is true in most practical cases, the nominal stress S_n across a diametral section at any load P as calculated by dividing the external bending moment by the section modulus is

$$S_n = \frac{0.955P}{t^2} \tag{52}$$

Derived in this way, this formula yields a kind of average stress, the stress concentration effect due to the presence of the hole being neglected. It is believed to offer a somewhat better indication of the load-carrying capacity of the spring under static loading conditions than the more commonly used eqs. 46 or 49.

Example 13. A Belleville spring is to be designed for a gasket application where the load is to be held approximately constant at 5000 to 6000 lb and where the deflection range due to temperature expansions will be around 0.09 in. Type of load deflection curve desired is that for $h/t = 1.5$ (Fig. 45). Space available will permit using an 8 1/2-in. OD and 4 1/4-in. ID spring. Maximum compression stress S_c (eq. 49) is limited to 220,000 psi.

In order to avoid the steep rise in the load near the flattened position, maximum deflection will be taken as 1.3 times the thickness, or $\delta/t = 1.3$. Taking $R = 4\,1/4$ in., $r = 2\,1/8$ in., $R/r = 2$, from Fig. 51, for $h/t = 1.5$, $\delta/t = 1.3$, $K = -5.1$. Taking $S_c = -220{,}000$ psi (compression), $E = 30 \times 10^6$ psi for steel, by solving eq. 49 for t and substituting these values, the required thickness t becomes

$$t = R\sqrt{\frac{S_c}{KE}} = 4.25\sqrt{\frac{-220{,}000}{-5.1 \times 30 \times 10^6}} = 0.161 \text{ in.}$$

From Fig. 48 for $h/t = 1.5$, $\delta/t = 1.3$, the load factor $C_1 = 1.67$, and from Fig. 47 for $R/r = 2$, the factor $C = 1.45$. Load per disk at $\delta = 1.3t$ or 0.21 in. is

$$P = \frac{C_1CEt^4}{R^2} = 2700 \text{ lb}$$

Using two springs in parallel, a load of twice this or 5400 lb is obtained which will be approximately constant within the deflection range desired.

WORKING STRESSES. Static Loading. Where Belleville springs are subject only to static or infrequently repeated loading, experience indicates that calculated stresses S_c ranging from 200,000 psi to as high as 375,000 psi for alloy steels as calculated from eq. 46 or eq. 49 may be used. Although these values seem extremely high, it should be remembered that such calculated stresses in most cases are localized near the upper inner edge of the spring (near A, Fig. 44). Consequently local yielding which will occur at such points when the load is applied will allow a redistribution of stresses so that the remaining portions of the spring can take a greater share of the load.

If the stress is figured using the nominal stress formula (eq. 52), the value should be kept well below the yield point of the material.

Fatigue Loading. For springs subject to fatigue or repeated loading, lower stresses should be used than for those subject to static loading. Although not many data are available, the indications are that Belleville springs made of good-quality spring steel will withstand repeated loading up to perhaps 500,000 cycles even for stresses as high as 200,000 psi calculated from eq. 49 (Ref. 5). For longer spring life or higher operating temperatures, it is necessary to use lower stresses.

It should be noted that the fatigue strength of Belleville springs may in general be increased by shot peening and presetting, and also by grinding the surfaces after heat treatment. Care must be taken to avoid surface cracking during this grinding operation.

MATERIALS used in the smaller sizes are SAE 1074, 1085, and 1095. For larger thicknesses and for highest quality, silico-manganese steel SAE 9260 or chrome-vanadium steel SAE 6150 are preferred. Phosphor bronze (spring temper) may also be used, in which case stresses about half those allowable for steel springs should be used and the modulus E should be taken as 15×10^6 psi.

9. SPRING MATERIALS AND PROPERTIES

The approximate chemical composition of various commonly used spring steels is given in Table 14.

Data on endurance ranges and physical properties for spring materials in torsion and bending obtained by various investigators are given in Tables 17 and 18. On each table, in addition to the limiting endurance range, pertinent information is given including kind of material, heat treatment, surface condition (i.e. whether ground and polished, or untouched), ultimate and yield strengths in tension, modulus of rupture, and yield strength in torsion. An endurance range of 0 to 110,000 psi as listed means that the bar will withstand indefinitely a stress range between these limits while completely reversed stress is indicated by the sign ±. For further information, refer to the footnotes below the tables.

Data given in Tables 17 and 18 indicate that, where the test specimen is ground and polished, a considerably higher endurance limit is obtained than where the surface is in the "as received" condition. This difference in endurance limits may probably be attributed largely to surface decarburization due to the heat-treatment process, although other factors (such as surface flaws or defects) may also be present. The various commonly used spring materials are described in the remaining pages of this chapter.

MUSIC WIRE. A high-quality carbon steel, this wire is widely used for small-sized helical springs, particularly those subject to severe stress conditions. The high strength of this material is obtained by using a steel of about 0.70 to 1.00% carbon, patenting and cold drawing to size. See Tables 14 and 15 for composition and properties. The tensile strength of music wire may vary from 255,000 psi for the larger wire sizes (0.16-in. diameter) to 440,000 psi for the smaller (0.005-in. diameter). In forming helical springs of music wire, the winding is done cold over a mandrel. After winding, it is advisable to give the springs a low-temperature heat treatment to relieve coiling stresses. This is usually done by heating the springs to a temperature of around 500 F for 1 hr for the larger sizes and for 15 to 30 min for the smaller sizes.

OIL-TEMPERED SPRING WIRE. This is a good-quality high-carbon steel wire, made by the open-hearth or electric-furnace process. In manufacturing, the wire is cold drawn to size and then heat treated. Tensile ultimate strengths vary from around 170,000 psi for the larger sizes (0.5-in. diameter) to around 310,000 for smallest sizes (0.025-in. diameter). Springs made of this wire are wound cold and then usually given a thermal treatment.

HARD-DRAWN SPRING WIRE. A carbon steel of lower quality than music or oil-tempered wire, this wire is used where the stresses are low or where a high degree of uniformity is not so essential. This material has tensile-strength properties slightly below that of oil-tempered wire. It should not, in general, be used where fatigue loading is involved.

ANNEALED HIGH-CARBON WIRE. This material, which has high ductility in the annealed state, is used where severe forming operations are necessary in the manufacture of the spring, for example in torsion springs with certain shapes of end turns. The springs are first formed from the annealed wire and then heat treated after winding to obtain the required physical properties. A typical composition calls for carbon 0.80 to 0.95%, manganese 0.50% max. See Table 15 for properties.

HOT-WOUND HELICAL SPRINGS HEAT TREATED AFTER FORMING. For the larger sizes of helical springs (say over $^3/_8$ to $^1/_2$ in. wire diameter) it is not practical to wind the springs cold. In such cases, the spring may be made from carbon or alloy steel bars wound hot and then heat treated. For winding these springs, ASTM specification A125-39 calls for heating to a temperature of 1700 F and coiling on a preheated mandrel. The springs are then allowed to cool uniformly to a black heat, after which they are heated uniformly to a temperature sufficient to refine the grain, and then oil quenched. After quenching they are tempered by heating to a temperature below the critical for a sufficient time to yield the required hardness values.

CHROME-VANADIUM STEEL WIRE. In the past this alloy steel wire has been frequently specified where a high-quality material is needed and where temperatures are somewhat higher than normal, as for automotive valve springs. It may be obtained either in the annealed or in the heat-treated condition. When wound from annealed wire, the springs must be heat treated after coiling. After winding from oil-tempered chrome-vanadium wire, a low-temperature heat treatment at around 500 to 700 F should be given, the higher bluing temperatures being preferred for applications involving elevated temperatures.

STAINLESS-STEEL (18-8) SPRING WIRE. Stainless steels having a composition of about 18% chromium and 8% nickel are widely used for springs subject to corrosion conditions, and are also of value for elevated temperature conditions. A typical specification for this material calls for the following composition:

Carbon, max	0.15%
Chromium	16.00 to 20.00%
Nickel	8.00 to 12.00%
Nickel plus chromium	26% min

The tensile strength of this wire is developed by cold drawing and may vary from 160,000 psi in 0.307-in. diameter size to 320,000 psi in the 0.01-in. diameter size. Springs are wound cold and stress relieved at 750 F for 15 min. to an hour, depending on wire size.

PHOSPHOR BRONZE. This material finds its greatest use where a spring with good electrical conductivity is desired; it is also used for applications where corrosion resistance is important. Typical physical properties are given in Table 16.

BERYLLIUM COPPER is an alloy consisting essentially of about 2% beryllium and the rest copper, together with small amounts of other alloys. It has the advantage of having a high electrical conductivity while not requiring any tin in its manufacture. In general, wire made from this material is quenched from 1475 F and then cold drawn to increase the hardness. After coiling, it is then heat treated to increase the physical properties. This heat treatment may also be varied to change the modulus of elasticity or the amount of drift or creep. Further data on the properties of this material are given in Table 16.

K-MONEL is a copper-nickel alloy to which 2 to 4% of aluminum has been added. A typical composition is copper 29%, nickel 66%, aluminum 2.75%. Wire made from this material is given a solution heat treatment and then cold drawn. After winding, the springs are given a final heat treatment to increase the hardness and strength. By this means ultimate strengths around 170,000 to 200,000 psi can be obtained. Springs made of this alloy are used for corrosion conditions and for resistance to elevated temperatures.

Z-NICKEL. A corrosion-resistant alloy containing about 98% nickel, Z-nickel is used for springs subject to elevated temperatures. Because it has a fair ductility after heat treatment, springs made of this material may often be wound from heat-treated wire. Further data are given in Table 16.

CLASSIFICATION OF BEARINGS

Bearings may be classified according to function, form, design, and lubrication.

CLASSIFICATION BY FUNCTION. Bearings may be defined according to function as follows:

Radial Bearing. A bearing applied to a rotating shaft to hold its axis in line, and prevent movement in a radial direction.

Thrust Bearing. A bearing applied to a shaft to prevent free endwise movement.

Angular Bearing. A bearing to constrain a shaft against both radial and axial movement; the load is received in an angular direction and has radial and axial components.

Guides or Ways. Bearings to permit and control the rectilinear movement of a sliding machine element, as a ram or crosshead, or slide. Guides usually are designed to prevent rotational movement of the sliding element.

CLASSIFICATION BY FORM. Bearings may be divided into the following forms, depending on the way in which friction is produced in them:

Sliding surface bearings include all that depend on lubricating films, perfect or imperfect, of oil, grease, graphite or other material.

Rolling contact bearings include all forms of ball and roller bearings.

Sliding rolling face bearings include those found in gear teeth, cams, and some forms of roller bearings.

CLASSIFICATION BY DESIGN may be made as follows:

Self-aligning bearings are those in which the parts will automatically align themselves when assembled and loaded.

Rigid Bearings. Bearings in which bearing surfaces are practically invariable in form and position after installation. Also known as nonaligning bearings.

Pivoted Segment Bearings. Bearings in which one of the active surfaces is made up of segments so freely mounted as to permit the formation of natural wedge-shaped lubricating films.

Elastic Bearings. Those in which one of the active surfaces is elastic or elastically supported so as to flex with respect to the other for the purpose of alignment and film formation.

CLASSIFICATION BY LUBRICATION. Bath Lubricated Bearings. Bearings in which active surfaces always are submerged in a well of lubricant.

Automatically Lubricated or Self-oiling Bearings. Bearings in which the rotation of the shaft or movement of parts causes lubricant to be applied continuously to the bearing surfaces.

Independent Pressure-lubricated Bearings. Bearings lubricated from a pressure source, independent of the bearing mountings, which may be operated before the machine is started, or may be geared into the machine, operating only when the machine runs. The system is then known as *automatic pressure lubrication.*

Periodically-lubricated bearings include all those using any form of intermittent application, by whatever means the lubricant is applied.

FACTORS IN BEARING DESIGN AND OPERATION. The several factors listed below are important to the designer and user of bearings, from the standpoint of permissible loads, lubrication, etc.

Surface speed rarely is a limitation with perfectly lubricated bearings. See Cooling of Bearings, Article 5 of this section.

Straight-line motion of sliding bearing surfaces may be continuous in one direction, as wire in a drawing die. It may be intermittent in one direction as in the ram of a ratchet jack. It may be reciprocating motion, as in crossheads or machine guides.

Circular sliding motion, as in journal, thrust, and angular bearings may be continuous in one direction, or it may be reversible, i.e., rotation in opposite directions for equal or unequal periods of time. It may be oscillating, as in a shaft carrying a rocking lever, or intermittent as in bearings for a ratchet wheel shaft. The angle of rotation is important in the last two classes.

Approach and recession of bearing faces frequently is superimposed on sliding motion, as in rocking levers, wrist pins, and reversing shafts. It is caused by change in magnitude of bearing load, by reversal, shock, or other cycle of load variation.

Rotating-radial load is found more often in vertical than in horizontal shafts. It is an unusual condition, generally due to lack of balance, accidental or otherwise, but it may result as in rock crushers from the process of manufacture carried on in the machine.

THE LOADING AND FRICTION OF BEARINGS ON FILMS OF LUBRICANT

By H. A. S. Howarth

1. PERFECT LUBRICATION OF BEARINGS

VISCOUS FLOW. Of the two opposite kinds of fluid flow *viscous* flow is simpler and easier to express mathematically, whereas *turbulent* flow is the more complex. Viscous flow of a fluid through a straight tube of uniform bore is straight-line flow, parallel with the axis of the bore.

Coefficient of viscosity is the measure of the resistance the fluid offers to the distortion its body undergoes under the action of the forces that cause the flow through the tube. Usually the term viscosity is used by itself. For mathematical calculations the viscosity is represented by the symbol μ, meaning the coefficient of viscosity. However, when the viscosity is said to be 200 SUS it is understood that 200 seconds were required for a standard quantity to pass by gravity through a short tube or jet known as the Saybolt universal viscometer. Such a measurement can be transformed into the absolute coefficient of viscosity by means of tables or charts and knowledge of the density of the fluid. (See p. 12-63.) Herein, however, the character μ will be assumed to represent the coefficient of viscosity.

For a discussion of *Reynolds' number* and its use in determining whether a fluid will have viscous or turbulent flow under the problem conditions, see p. 13-02.

Viscosity Units. Figure 1 illustrates an element of the fluid within a film whose flow is viscous. The film, of which the element is but a small part, can be thought of as flowing between two parallel plates whose distance apart is h. One plate may be thought of as stationary and the other as moving over it with some known velocity U.

The element to be examined is assumed to have a square unit of area, parallel with the plates, and a differential thickness dh. The forces acting on the element give one of its faces a velocity that is higher than the other by a differential amount dU in the direction indicated. The force that causes this velocity increase of the unit area is represented by f. The ratio dU/dh is called the rate of distortion of the fluid. The coefficient of viscosity is defined as the ratio of the force f, upon a unit area, to the rate of distortion it produces in the fluid. Thus

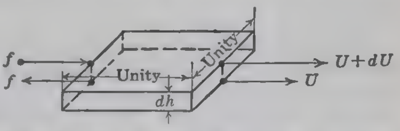

Fig. 1. Forces and velocities in viscous flow.

$$\mu = \frac{f}{dU/dh} \tag{1}$$

If the rate of distortion is uniform throughout the film thickness h, the value of μ could be determined by eq. 1. Conversely, when μ is known, f can be found from $f = \mu U/h$.

For the convenience of those who wish to convert the coefficient of viscosity μ from one system of units to another, the following relationships may be used. The three units commonly employed vary in magnitude, from greatest to least, from the Reyn, to the poise, to the centipoise, in the ratio 6,900,000 to 100 to 1. The Reyn expresses viscosity in pounds, seconds, per square inch.

One Reyn equals 69,000 poises or 6,900,000 centipoises. Therefore if the viscosity of an oil is 3.4×10^{-6} Reyns, it is 0.2345 poise, or 23.45 centipoises.

Commercial Viscosities. Viscosities are commonly measured commercially by instruments that use the weight of the oil as the means of forcing it through a jet. Such readings involving volume and time are convertible directly into what is termed kinematic viscosity, whose units, *stoke* and *centistoke*, parallel the poise and the centipoise. The density of the liquid multiplied by the kinematic viscosity gives the absolute coefficient of viscosity in units that are required for engineering calculations. The Reyn, the poise, and the centipoise are units of absolute viscosity (viscosity coefficients) and may be used in engineering calculations without correction for density. For commercial viscosities, see p. 12-63.

Viscous Flow through Tubes (Fig. 2). Assuming no molecular slippage at the tube surface and not including entrance and discharge losses, the laws of viscous flow yield the following formulas: V_r = volume of flow through tube; t = time required, seconds; P_1 and P_2 = respectively, the pressures acting upon the liquid at entering and discharging ends of tube; h = diameter of the tube bore; L = length of tube; u = linear velocity of flow at a distance y from the tube bore radially.

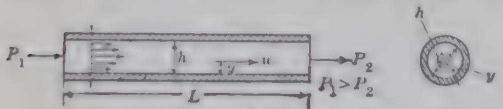

FIG. 2. Viscous flow through tube.

$$\frac{V_r}{t} = \frac{\pi h^4(P_1 - P_2)}{128\mu L} \tag{2}$$

$$u = \frac{(P_1 - P_2)(hy - y^2)}{4\mu L} \tag{3}$$

Viscous Flow between Stationary Parallel Plates (Fig. 3). Assuming no molecular slippage at the plate surfaces and not including entrance or discharge losses, the laws of viscous flow yield the following formulas: V_p = volume of flow through space between plates, neglecting influence of the sides; t = time required, seconds; P_1 and P_2 = respectively, the pressures at entrance and discharge; h = uniform distance between inner faces of plates; L = length of plates in direction of flow; b = their width; y = a distance from one plate face at which the velocity of flow u is to be determined.

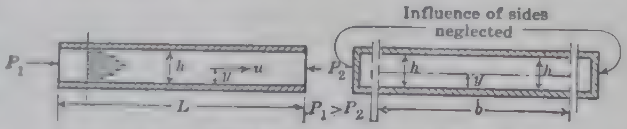

FIG. 3. Viscous flow between parallel plates.

$$\frac{V_p}{t} = \frac{bh^3(P_1 - P_2)}{12\mu L} \tag{4}$$

$$u = \frac{(P_1 - P_2)(hy - y^2)}{2\mu L} \tag{5}$$

Viscous Flow from Approaching Parallel Plates (Fig. 4). The time rate at which two parallel flat surfaces will approach each other when the space between them is filled with a viscous liquid, when the plates are elliptical with no central cavity, and when no oil is added, and when the upper plate moves downward under a constant normal load R, was found by Osborne Reynolds to be:

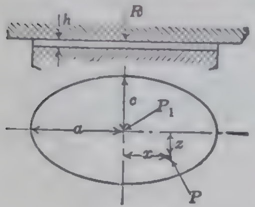

FIG. 4. Approaching parallel faces with oil film between them.

$$t = \frac{3\mu\pi a^3c^3}{2R(a^2 + c^2)}\left\{\frac{1}{h_1^2} - \frac{1}{h_2^2}\right\} \tag{6}$$

$$P_4 = \frac{2R}{\pi ac} \tag{7}$$

$$P_5 = -\frac{2R}{\pi ac}\left\{\frac{x^2}{a^2} + \frac{z^2}{c^2} - 1\right\} \tag{8}$$

The symbols a and c are, respectively, the semimajor and semiminor axes of the elliptical faces. x and z are the coordinates of any point measured respectively from the c and a axes. R is the total load on the plate. h_1 and h_2 are the distances between the plates at the start and the finish of the time interval t. P_4 is the pressure at the center of the plates. P_5 is the pressure at any point whose coordinates are x and z.

Separation of Circular Plates by High-pressure Oil (Fig. 5). One plate may be considered to be flat and to extend beyond the other, but to press upon it with a load R. The lower plate is assumed to be circular and flat, with a smaller circular recess at its center, and into which oil is assumed to be forced from below with a pressure sufficient to cause a radially outward flow between the parallel faces of the plates that will hold them apart a distance h. The pressure of the oil supply to the recess is P_1. The recess radius is r_1. The outer radius of the circular face is r_2. At any other radius r the pressure will be P. The average pressure over the surface πr_2^2 will be $P_0 = R/\pi r_2^2$. The gallons of oil

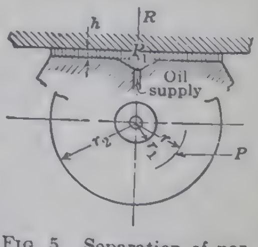

FIG. 5. Separation of parallel faces by high-pressure oil.

per minute supplied to the recess to hold the faces apart a distance h will be G. The coefficient of viscosity of the lubricant, μ, will be expressed in pounds per square inch (Reyns). Linear dimensions are in inches and pressures in pounds per square inch in the formulas that follow.

Case 1. **The load is carried by a continuous flow of oil:**

$$G = \frac{0.0867h^3R}{\mu(r_2^2 - r_1^2)} \tag{9}$$

$$P_1 = \frac{2R \log_e\left(\frac{r_2}{r_1}\right)}{\pi(r_2^2 - r_1^2)} = \frac{7.35\mu G \log_e\left(\frac{r_2}{r_1}\right)}{h^3} \tag{10}$$

$$P = \frac{2R \log_e\left(\frac{r_2}{r}\right)}{\pi(r_2^2 - r_1^2)} \tag{11}$$

$$\frac{P_1}{P_0} = \frac{2r_2^2 \log_e\left(\frac{r_2}{r_1}\right)}{r_2^2 - r_1^2} \tag{12}$$

Case 2. The oil supply is stopped and the plates move toward each other. In time t seconds the distance between the plates reduces from h_2 to h_1 under load R.

$$t = \frac{3\mu\pi(r_2^4 - r_1^4)}{4R}\left\{\frac{1}{h_1^2} - \frac{1}{h_2^2}\right\} \tag{13}$$

$$P_1 = \frac{2R}{\pi(r_2^2 - r_1^2)} \tag{14}$$

$$P = \frac{2R(r_2^2 - r^2)}{\pi(r_2^4 - r_1^4)} \tag{15}$$

Friction and Viscosity in Films of Uniform Thickness. The relation between friction and the viscosity of the lubricant in bearings seems to have been first pointed out in 1883 by Petroff (Ref. 1), who assumed that a journal runs concentrically in a sleeve bearing. He suggested that there might be slippage between the lubricant and the bearing surfaces. Hence the formula he proposed was not so simple as the one that follows, in which slippage is taken as zero.

At high speed a journal, if lightly loaded, will run very nearly concentric in a 360° bearing sleeve uninterrupted by grooves, if copiously supplied with oil (Fig. 6). If the journal radius is a, the radial clearance h, the sleeve width b, and the rpm is N, the viscous tangential frictional resistance to rotation will be F as follows:

$$F = 2\pi abf \tag{16}$$

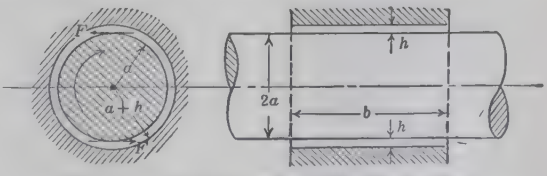

Fig. 6. A journal, central within its bearing.

It was pointed out that, when the viscosity coefficient μ is known, the relation $f = (\mu U/h)$ evolves from eq. 1. In this equation $U = (2\pi aN/60)$. If these are combined with eq. 16 there emerges the simple 360° bearing friction formula:

$$F = \frac{\mu\pi^2a^2bN}{15h} \tag{17}$$

This equation leaves out of account the frictional resistance offered by the oil-flow due to the pressure gradient. With concentric operation, constant viscosity, and no load, there would be no pressure gradient.

If the viscosity coefficient μ in eq. 17 is expressed in Reyns (pounds, seconds, per square inch) and the linear dimensions are in inches, F will be in pounds. If the viscosity is expressed in poises (dynes, seconds, per square centimeter) and linear dimensions in centimeters, the force F will be in dynes. If the viscosity is expressed in centipoises and linear dimensions are in centimeters, the force F will be hundredths of dynes.

ANALYSES OF THE WEDGE-SHAPED OIL FILM. Oil films in bearings are not so simple in shape as the one of uniform thickness described above. It has long been known that the film in a bearing should be wedge shaped in order best to develop pressures necessary to support a substantial load without metallic contact during rotation. (See Refs. 2, 3, 4, 5.)

Continuity of Flow with Various Film Shapes, without Side Loss. The theory underlying film form in bearings is really not difficult to understand when examined from the viewpoint of continuity of forward viscous flow, with absence of side leakage loss of lubricant. There are of course such side losses, which will be discussed later. The present approach, however, is simpler without them.

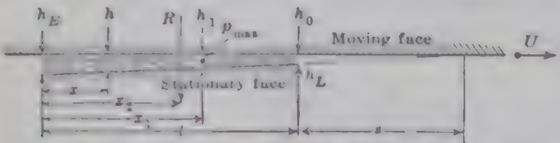

FIG. 7. Wedge film between two inclined flat faces.

In the following résumé, covering several film forms whose cross sections are seen in Figs. 7 to 16, the film is assumed to be held stationary for observation of its contour, the study of its pressure distribution, and the positioning of the line of action of the load it carries. The velocities of the bearing faces are represented by vectors for direction and relative magnitude. The positions indicated for load line R, least film thickness h_0, and the film thickness h_1 at the point of maximum pressure are approximate. All films are shown for the same length l, throughout which the pressure rises from P_E at h_E to its maximum at h_1 and then falls off to P_L at h_L. Initial and final film pressures depend upon the environment in which the film functions and is required to carry its load.

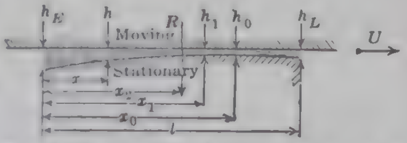

FIG. 8. Wedge film between a flat and a curved face.

Film faces may be flat or curved or a combination of the two. For the purpose of analysis any film having two curved faces can be shown as having one flat and one curved. However this résumé shows the films in their actual forms, with thicknesses highly exaggerated.

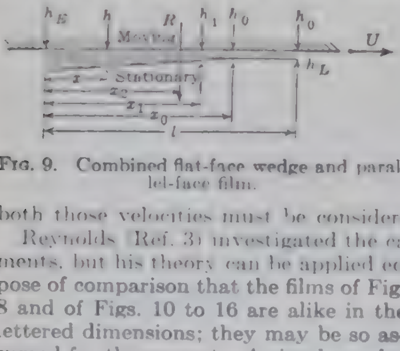

FIG. 9. Combined flat-face wedge and parallel-face film.

In Figs. 7, 8, and 9 only one face is shown to be moving. Its velocity is U with respect to the load line R. If the other face has any velocity it moves with the load line and relative to it has a velocity of zero. However, when both surfaces of the film have velocities with respect to the load line, with which the pressure film must remain, both those velocities must be considered. They appear as U_1 and U_2 in Figs. 10 to 16.

Reynolds (Ref. 3) investigated the cases of Figs. 7 and 8 in his study of Tower's experiments, but his theory can be applied equally well to the others. It is conceivable for purpose of comparison that the films of Fig. 8 and of Figs. 10 to 16 are alike in the lettered dimensions; they may be so assumed for the present. A simple analysis will then indicate their relative abilities to support a load.

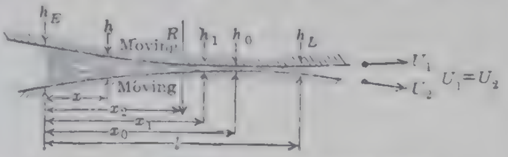

FIG. 10. Film separating rolling faces.

The volume of oil that enters a film in a given time will pass the region of greatest fluid pressure in the same time if there is no change of density and no lateral change of film pressure. Therefore a unit width of the film can be considered as representative of the whole, so long as the cross section is uniform and so long as side leakage is negligible. In fact the extent to which side leakage reduces the capacity of a film is conveniently expressed by a percentage of the ideal capacity, as will later be explained. (See p. 12-09.)

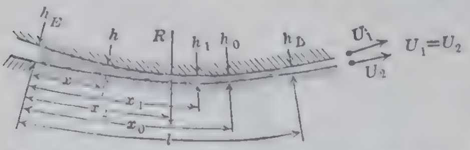

FIG. 11. Film separating internally rolling faces.

The net rate of flow of oil past any section of the film will be equal to the algebraic sum of the flows due to the several causes of flow. Two such causes are, first, the velocities of the film faces with respect to the load line and, second, the pressure gradient. At the region of maximum pressure the gradient will be zero and the total flow will be due to relative motion of the film faces. Thus the following equation can be written:

$$\frac{Q_1}{t} = \frac{Q_m}{t} + \frac{Q_p}{t} \tag{18}$$

where Q_1 is the rate of flow where the pressure is greatest; at this point the film thickness is h_1, which lies at distance x_1 from the beginning of the film where the thickness is marked h_E. At any other distance x, where the film thickness is h, the forward flow will be $Q_m/t + Q_p/t$. Thus eq. 18 is a statement of the law of continuity of flow in simple terms.

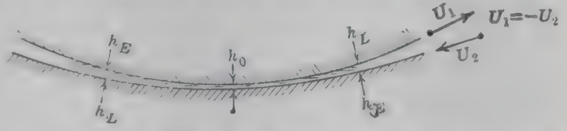

FIG. 12. Film between two faces having equal but opposite speeds past line of action of the load R.

The rate of flow Q_m/t, due to relative motion, will obviously be $Uh/2$ per unit of film width for films of Figs. 7, 8, and 9. The rate of flow Q_p/t, due to the pressure gradient, can be taken from the previous study of parallel plate flow (p. 12-04) placing width b at unity. Thus

$$\frac{Q_p}{t} = -\frac{h^3}{12\mu}\left\{\frac{dp}{dx}\right\} \tag{19}$$

Inserting these values in eq. 18 yields the following equation when solved for dp/dx.

$$\frac{dp}{dx} = \frac{6\mu U(h - h_1)}{h^3} \tag{20}$$

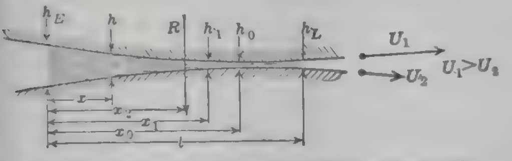

FIG. 13. Film separating faces that roll and slide.

The law of variation of h with x is clear for the film of Fig. 7. If C is the slope factor, $h = C(l + s - x)$ and from eq. 20 there emerges

$$\frac{dp}{dx} = \frac{6\mu U(x_1 - x)}{C^2(l + s - x)^3} \tag{21}$$

In order to obtain similar definite equations for other films than Fig. 7 it is necessary likewise to define the relation of film thickness to its position in the film. Equation 20 is therefore general for films like Figs. 7, 8, and 9, where U is the only velocity. Extensive analyses of films like Fig. 8 have been made as will appear later in data on journal bearings with running clearance and on those whose surfaces are fitted. (See p. 12-16.) The data that appear later (p. 12-33) on pivoted shoes were obtained from an extension of the study of Fig. 7 and its eq. 21.

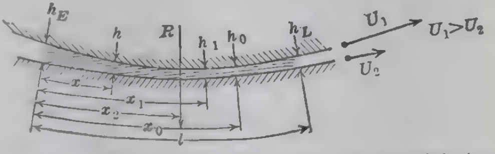

FIG. 14. Film between faces that roll and slide internally.

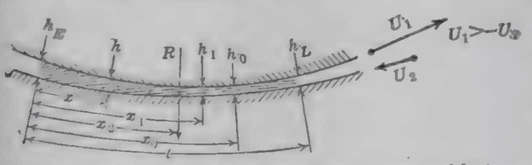

FIG. 15. Film between two faces having unequal but opposite speeds past line of action of the load R.

Before proceeding with examination of more complicated films it will be profitable to study Fig. 9. In that figure a film is illustrated that has a beveled or wedge-shaped beginning and a pair of flat parallel faces for an ending, with no interruption where they join. Between the flat faces of the wedge portion the relation (eq. 19) will hold. Beyond h_{01}, i.e., in the parallel portion, the flow will be of uniform rate, which is the sum of the two forward flows, the total equaling $Uh_1/2$. They are $Uh_0/2$ and $\frac{h_0^3}{12\mu}\frac{(P_{01} - P_{02})}{(l - x_0)}$. Therefore

$$\frac{Uh_1}{2} = \frac{Uh}{2} - \frac{h^3}{12\mu}\left(\frac{dp}{dx}\right)$$
$$= \frac{Uh_0}{2} + \left(\frac{P_{01} - P_{02}}{l - x_0}\right)\frac{h_0^3}{12\mu} \tag{22}$$

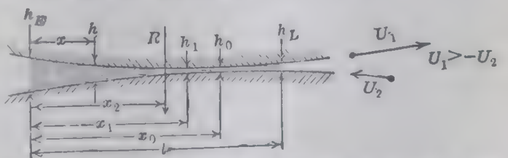

FIG. 16. Film between two convex cylindrical faces having unequal opposite speeds past line of action of the load R.

Ordinarily P_{02} would be zero and P_{01} only a little less than P_{max}. In this particular combined film the maximum pressure will be much closer to the thin end of the flat wedge than in the plain flat-wedge film of Fig. 7. Obviously this film approaches the full flat wedge in form as the flat parallel-faced portion becomes shorter.

Thus far we have been dealing with films having one fixed face and one face that moves over it with velocity U. However, it is possible to have pressure developed in films between two faces that move in the same general direction with equal speed past the load line R and the zone of closest approach. This is most easily visualized by two slightly curved faces rolling upon each other but separated by a film of oil as in Fig. 10. Obviously the length of the pressure region of the film would be short relative to the radii. The less the radius of curvature, the shorter the film. If the centers of curvature are on the same side of the film as in Fig. 11, and the radii are only slightly different, the film might fill the space between the rolling members completely. One member would be rolling around inside the other, or both would turn about separate but parallel noncoincident axes.

For the general case of Figs. 10 and 11 the first fundamental eq. 18 will serve as a starting point, but the rate of flow at the region of maximum pressure will be twice as great as for Figs. 7, 8, and 9. Q_1/t will be equal to $\frac{(U_1 + U_2)}{2} h_1$, instead of $Uh_1/2$, when $U = U_1 = U_2$. Therefore the equations that apply to Figs. 10 and 11 will be:

$$\frac{(U_1 + U_2)h_1}{2} = \frac{(U_1 + U_2)h}{2} - \frac{h^3}{12\mu}\left(\frac{dp}{dx}\right) \tag{23}$$

$$\frac{dp}{dx} = \frac{6\mu(U_1 + U_2)(h - h_1)}{h^3} \tag{24}$$

Comparison of eqs. 20 and 24 shows the pressure gradients to have the ratio of $U:(U_1 + U_2)$. This means that when two surfaces roll together without slip, and without contact, their ability to carry a load, upon a film of given viscosity and dimensions, will be in the ratio $(U_1 + U_2)/U$ to the ability of the same film when one of its faces moves with velocity U and the other is stationary, with respect to the load line R.

Figures 13 and 14 show that their velocity vectors indicate combined rolling and sliding. U_1 is drawn equal to $2U_2 = 2U$. Hence the pressure gradient would be three times that of eq. 20. However, when the velocity vectors are not pointed in the same direction their sum is less in the positive direction, or it is zero, or it is net negative. Thus in Figs. 15 and 16 the sum is net positive, whereas in Fig. 12 it is zero. The film of Fig. 12 would carry no load, i.e., it would develop no pressure.

Dynamic Loads upon Bearings. The film forms shown by Figs. 7 to 16, while not exhaustive, cover most of the best films available to the machine designer for preventing the wearing away of the bearing surfaces if they can be adequately lubricated. Such films form between the surfaces that move across the load line with suitable velocities, and they obviously vary in length inversely with the rate of change of film thickness, if not interrupted by termini.

When films are studied in dynamically loaded bearings, in which the load line changes location rapidly and in cycles, with respect to other motions of the bearing faces, all motions must be determined with respect to the load direction and position. Such a study of the bearings of the crank-engine linkage is very important and is being made the subject of careful research. Important papers have been presented in recent years, as, for example, paper by J. M. Stone and A. F. Underwood (Ref. 6) of General Motors Research Division, and paper by Professor J. T. Burwell (Ref. 7) of Massachusetts Institute of Technology. To supplement these analytical studies extensive tests have been made and are continuing to be run in an effort to bring experience and analysis into agreement.

Pivoted Shoe Bearings. Before the integration of the fundamental equations are discussed, the independent inventions of pivoted shoe bearings should be noted, by Kingsbury first and by Michell second, a very few years apart, the one at Durham, New Hampshire, U.S.A., and the other at Melbourne, Australia. Both inventors acknowledge indebtedness to Osborne Reynolds' mathematical analysis of the flat-wedge film in connection with his study of Tower's experiments.

There is a vast difference between a fixed bevel thrust bearing and the variable bevel obtained with pivoted thrust shoes. The latter can adjust its wedge taper and film thickness to match the requirements of varying load, speed, and oil viscosity, whereas the fixed bevel thrust bearing cannot vary its wedge taper, and therefore is not so widely useful. When it slows down to a stop its film loses pressure rapidly and comes to a stop suddenly. Conversely, when started up it has to reach its designed speed before its film will have its best form.

Capacity and Friction of Flat-wedge Films. The integration of the pressure gradient equation for the flat-wedge film, made by Reynolds himself, is summarized and set down accurately by Kingsbury (see Ref. 8). Kingsbury pointed out, as others had done, that Reynolds ignored the pressure gradient effect upon friction, and that the friction equation should be:

$$f = \frac{\mu U}{h} + \frac{h}{2}\left(\frac{dp}{dx}\right) \tag{25}$$

The friction is seen to be due to the sum of two rates of distortion of the film at the bearing or journal surface. The first and larger (usually) is the distortion due to relative motion of the bearing faces and the second is the distortion due to the forward or backward flow of the lubricant due to the pressures within the film.

For the flat-wedge film of Fig. 7 the friction F for a unit width is readily found to be

$$F = \frac{\mu U s}{h_0}\left[4 \log_e\left(\frac{l+s}{s}\right) - \frac{6l}{l+2s}\right] \tag{26}$$

The preliminary analysis of the flat-faced wedge film made by Osborne Reynolds has become the basis for the mathematical calculations required for the application of such films to straight-line motion as in cross heads and planers, and to rotary motion as in thrust bearings, especially those of the Kingsbury and Michell types.

It must be borne in mind that the terms "flat-wedge film" and "pivoted shoe film" are not necessarily synonymous, although it is usual to assume that the pivoted shoe films have the flat-faced wedge form, and to apply to them the formulas developed for it. Flat-wedged films are extensively examined in subsequent discussions.

Capacity and Friction of Journal-bearing Films. Reynolds next applied his analysis to Tower's experimental partial journal bearing which was assumed to have running clearance (see Ref. 3). Reynolds showed that his hydrodynamical theory explained Tower's results, as to friction and film pressures, provided the film of lubricant had a curved wedge form.

The analytical studies of journal-bearing films of various angular extents was carried forward by later investigators (see Refs. 9, 10, 11).

THE EFFECT OF SIDE LEAKAGE UPON CAPACITY AND FRICTION. Up to this point of our discussion the effect of side leakage has been neglected and our formulas have been given for a unit of width of a film so wide (infinite) that only forward or backward flow need be considered. The actual flow in a film of finite width is best illustrated by means of a flat-wedge film, three views of which are shown in Fig. 17. In the plan view the oil flow is indicated by curved arrow-headed lines. Obviously the narrower the width b relative to a given length l the greater will be the proportionate oil loss at the sides of the film, and the less will be the pressures developed in the film.

Kingsbury proposed the character L_1 for representing the ratio of actual to ideal carrying capacity of a film. He also proposed that F_1 represent the ratio of the actual to the ideal friction loss of the film. Both these "correction factors," as they are called, vary with the ratio of film length to film width represented by the characters l/b.

FIG. 17. The flat-wedge film. (H. A. S. Howarth, The Loading and Friction of Thrust and Journal Bearings with Perfect Lubrication. *ASME Trans.*, MSP-57-2, 1935)

In Fig. 18 Kingsbury's factors for L_1 and F_1 are shown for easy reference in the solving of problems that will be given later with the study of charts of bearing capacities. The side leakage curves by Needs (Ref. 12) in Fig. 19 were prepared specifically for 120° centrally loaded journal bearings and may be used for correction factors when solving problems involving such bearings, as will also appear later.

OPTIMUM CHARACTERISTICS OF OIL FILMS IN BEARINGS. Effects of Deviations. Reynolds pointed out in his early studies that a certain shape of wedge film would carry the greatest load. This is true also for the curved wedge films of journal bearings. Special studies of optima have shown that there are others than that for capacity. It has also been learned how far these optima may be deviated from with impunity. A study of optima for the flat-wedge film follows.

Optima for Flat-wedge Films. The flat-wedge film itself is illustrated by three views in Fig. 17. Its characteristics of load and friction with relation to film shape are shown in Fig. 20.

Variation in film form can best be visualized by keeping the length l and the minimum thickness h_0 unchanged and then changing the distance s. This will of course change h_m. Such changes in the film form will change its load-carrying capacity and the frictional resistance offered by the film to motion of the moving face, for cases where there is no other change of condition such as viscosity or speed.

If the load-carrying capacity, for example, should vary, under the above changing con-

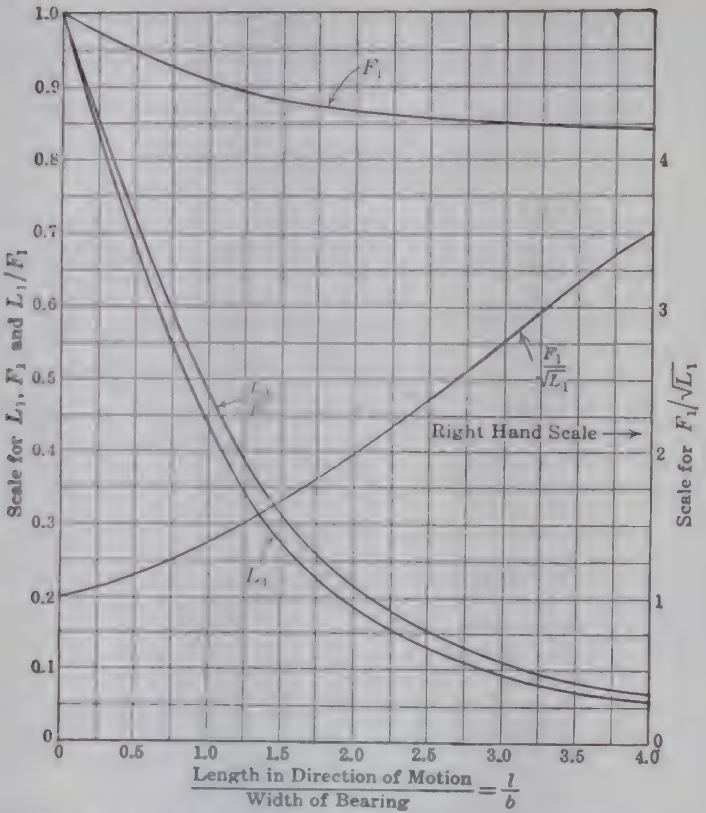

FIG. 18. Correction factors for influence of side leakage on load-carrying capacity and friction of fluid film. (Albert Kingsbury, Optimum Conditions in Journal Bearings, *ASME Trans.*, RP-54-7, 1932)

ditions as to film form, in such a way that it passes through a maximum value, the length s at which it occurs, when divided by the length of the shoe l, will give a ratio M that may be called an optimum. Curve 2 in Fig. 20 has such a maximum ordinate when $M = 0.841$. It belongs to the group of variables given in the equation for curve 2, whose ordinate Y is seen to be proportional to the square root of the load (Fig. 20). When $M = 0.841$ the film will carry the greatest load for a minimum thickness h_0. This will be called Case 2 optimum.

If the total frictional resistance offered to the carrying of a given load should vary in such a way that it passes through a minimum value, as the ratio M varies, the particular M ratio at which this minimum occurs may be considered desirable and be named an optimum one. In curve 1 there is seen to be such a minimum ordinate when $M = 0.484$. It belongs to the group of variables given in the equation for curve 1 whose ordinate Z is seen to be proportional to the friction. When $M = 0.484$ the film will carry a given load with the least frictional resistance. Nothing is said about the film thickness, but it is obvious from the preceding paragraph that for this value of $M = 0.484$ the thickness h_0 must be less than it was when $M = 0.841$. Thus the film form for least frictional resistance will not be the same as

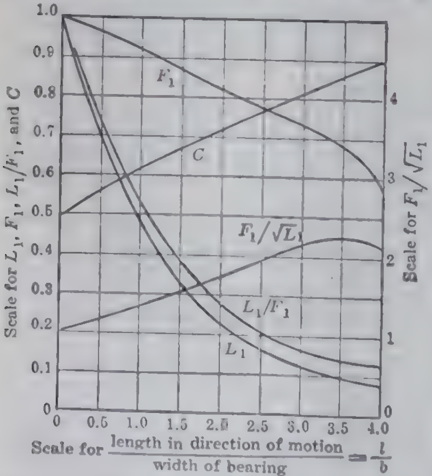

FIG. 19. Side leakage factors for optimum 120-degree central bearings for minimum coefficient of friction. (S. J. Needs, Effects of Side Leakage in 120-degree Centrally Supported Journal Bearing, *ASME Trans.*, APM-56-16, 1934)

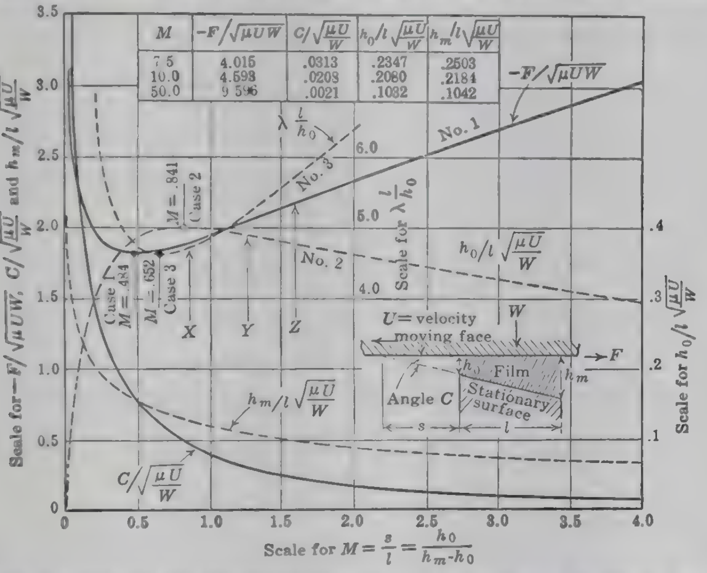
the film form for maximum capacity. However, when $M = 0.484$ the friction will be least for carrying a given load. This will be called Case 1 optimum.

There is one other curve (No. 3) in Fig. 20 that has a minimum point. It represents the group of variables involving the coefficient of friction and a function of the angle of the film wedge. For a film of length l the ratio of friction coefficient λ to minimum film thickness h_0 will have a minimum value when $M = 0.652$. This minimum is called by Kingsbury the optimum friction coefficient condition and Case 3. It should be noted that it is not the same as Case 1.

Figure 20 shows that the minimum film thickness h_0 will vary directly as Y for a series of films of same length l carrying the same load at the same speed, the films having the same average viscosity. Hence for Cases 1, 2, and 3, already discussed, the thicknesses h_0 are not very different, but where $M = 50$ (see table at top of Fig. 20), the thickness h_0 is about one-fourth of the average of the first three values.



M	$-F/\sqrt{\mu UW}$	$C/\sqrt{\frac{\mu U}{W}}$	$h_0/l\sqrt{\frac{\mu U}{W}}$	$h_m/l\sqrt{\frac{\mu U}{W}}$
7.5	4.015	.0313	.2347	.2503
10.0	4.598	.0208	.2080	.2184
50.0	9.596	.0021	.1082	.1042

FIG. 20. Effect of deviations from optimum conditions for a bearing with flat-wedge films. (H. A. S. Howarth, *ASME Trans.*, MSP-57-2, 1935)

Case 4 is interesting because it has a convenient value of M which is unity. Hence its mean thickness would be 50% greater than its h_0, and its maximum thickness would be twice its minimum, i.e., $h_m = 2h_0$. This case and the examples tabulated at the top of Fig. 20 are of interest in any study of the effects of deviations from "optimum" conditions.

In the solving of certain bearing problems the mean film thickness is often needed. Values are listed below for the four cases most frequently referred to:

Case 1	Case 2	Case 3	Case 4
$h_1 = 2.033h_{01}$	$h_2 = 1.594h_{02}$	$h_3 = 1.765h_{03}$	$h_4 = 1.5h_{04}$

The meaning of the subscripts in this tabulation and in Table 1 is, for example, that for Case 2 the mean film thickness, represented by h_2, is 1.594 times the least film thickness represented by h_{02}.

Application of Side Leakage Correction Factors. In formulas given for X, Y, and Z (Fig. 20) no correction has been made for side leakage. Hence it is necessary to introduce into them in the proper manner the correction factors L_1 and F_1. In Case 2 it is found convenient to square the terms. The corrected formulas are:

$$\frac{\lambda l}{h_0} = \frac{XF_1}{L_1} \tag{27}$$

$$\frac{h_0^2 W}{l^2 \mu U} = Y^2 L_1 \tag{28}$$

$$\frac{F}{\sqrt{\mu UW}} = \frac{ZF_1}{\sqrt{L_1}} \tag{29}$$

There have been grouped together in Table 1 certain formulas useful for solving problems involving flat-wedge films, especially those of pivoted shoes when arranged in a ring whose mean diameter is d. The only new term to appear besides d is P_0, which means the average pressure acting on the face of a pivoted shoe. The mean circumferential length of one such shoe would be l. The load carried by a circumferential band of unit radial width on diameter d would be

$$lP_0 = W \tag{30}$$

The velocity U at the mean diameter d can be related to rpm by the relation in eq. 31.

$$U = \frac{\pi d N}{60} \tag{31}$$

The optimum formulas are given in Table 1 for Cases 1, 2, 3, and 4.

Table 1. Formulas for Flat-wedge Films

Case 1

$$\lambda_1 = 1.815 \frac{F_1}{\sqrt{L_1}} \sqrt{\frac{\mu U}{p_0 l}} \tag{32}$$

$$\lambda_1 = 0.415 \frac{F_1}{\sqrt{L_1}} \sqrt{\frac{\mu d N}{p_0 l}} \tag{33}$$

$$h_{01}^2 = \frac{0.00763 L_1 \mu d l N}{p_0} \tag{34}$$

$$h_1^2 = \frac{0.0315 L_1 \mu d l N}{p_0} \tag{35}$$

Case 2

$$\lambda_2 = 1.890 \frac{F_1}{\sqrt{L_1}} \sqrt{\frac{\mu U}{p_0 l}} \tag{36}$$

$$\lambda_2 = 0.432 \frac{F_1}{\sqrt{L_1}} \sqrt{\frac{\mu d N}{p_0 l}} \tag{37}$$

$$h_{02}^2 = \frac{0.00837 L_1 \mu d l N}{p_0} \tag{38}$$

$$h_2^2 = \frac{0.0213 L_1 \mu d l N}{p_0} \tag{39}$$

Case 3

$$\lambda_3 = 1.845 \frac{F_1}{\sqrt{L_1}} \sqrt{\frac{\mu U}{p_0 l}} \tag{40}$$

$$\lambda_3 = 0.422 \frac{F_1}{\sqrt{L_1}} \sqrt{\frac{\mu d N}{p_0 l}} \tag{41}$$

$$h_{03}^2 = \frac{0.00815 L_1 \mu d l N}{p_0} \tag{42}$$

$$h_3^2 = \frac{0.0254 L_1 \mu d l N}{p_0} \tag{43}$$

Case 4

$$\lambda_4 = 1.950 \frac{F_1}{\sqrt{L_1}} \sqrt{\frac{\mu U}{p_0 l}} \tag{44}$$

$$\lambda_4 = 0.446 \frac{F_1}{\sqrt{L_1}} \sqrt{\frac{\mu d N}{p_0 l}} \tag{45}$$

$$h_{04}^2 = \frac{0.00830 L_1 \mu d l N}{p_0} \tag{46}$$

$$h_4^2 = \frac{0.0187 L_1 \mu d l N}{p_0} \tag{47}$$

The foregoing study of flat-wedge films has been fairly comprehensive because of their simplicity and fundamental importance. It is, however, only in straight-line motion that the film can have a true flat-wedge shape. In rotary motion the film form, in its circular section, will follow the sine curve wedge form in thrust bearings and in journal bearings with clearance, and the fitted surface wedge form in fitted cylindrical journal bearings. Two such film forms are shown in Figs. 21 and 22 as they are found in common types of journal bearings not having pivoted shoes.

In thrust bearings of the pivoted shoe type the sine curve shape of the film wedge section varies in thickness and node range, not only with the radius to the circular section examined, but also with changes in speed of rotation, or of viscosity of lubricant. For example, as a pivoted shoe thrust bearing slows down, the surfaces come closer together until they eventually meet with the fit originally provided, usually flat to flat. Obviously one important virtue of the pivoted shoe thrust bearing is that ability to adjust its film thickness and form (wedge angle) to suit all operating conditions, from zero velocity to high speed, from low to high film viscosity, and also from light to heavy load. The study of pivoted shoes is continued in more detail later, and loading tables will be given together with safe minimum film thicknesses.

An ordinary journal bearing with running clearance, however, must come to rest on the line of contact between two surfaces of different curvature. Hence its carrying capacity at zero speed would be expected to be less than that of fitted surfaces. Journal bearings are therefore frequently made with fitted surfaces, or with combined fitted and clearance surfaces, as well as with true cylindrical surfaces with running clearance.

CAPACITY AND FRICTION DETERMINATION FOR JOURNAL BEARINGS. As already stated, Osborne Reynolds made the first analysis of such a bearing in his hydrodynamical study of Tower's test bearing. The latter was assumed by Reynolds to be what is now generally called a *partial bearing with running clearance.* In practice such bearings have film arcs varying from 60 to 360°, the latter being called a *full bearing.* When the load upon such a bearing bisects the film the bearing is said to be *centrally loaded.* When the leading angle of the film is longer than the trailing angle the bearing is said to be *eccentrically loaded.* There are widely differing series of eccentrically loaded bearings. They are defined by the α/β ratio, α being the leading angle of the film and β its total angle. When $\alpha/\beta = 0.5$ the bearing is centrally loaded.

Sommerfeld (Ref. 9), using polar coordinates, analyzed a 360°, or full, clearance bearing and also a 180° centrally loaded bearing.

Harrison (Ref. 10) later made an analysis of the 360° clearance bearing, in rectangular coordinates, for the purpose of studying Kingsbury's air bearing test results, as already mentioned. Harrison's equations led Howarth to make his graphical analysis (Ref. 11) based upon them, covering bearing film arcs less than 360°.

Graphical Integrations for General Characteristics. This graphical analysis deserves careful note because it points the way for integration of any differential ratio, especially of one whose exact mathematical integration is either formidable or impossible. The pressure gradient eq. 21 can be applied to a full or 360° clearance bearing as was done by Harrison, who took as the origin for the angular positions of any film thickness h, the location of maximum value of h. Then when $x = a\theta$ and $h = \eta(1 + c\cos\theta)$, eq. 21 becomes

$$\frac{dP}{d\theta} = \frac{6\mu Uac(\cos\theta - \cos\theta_1)}{\eta^2(1 + c\cos\theta)^3} \tag{48}$$

In eq. 48 a is the journal radius and $(a + \eta)$ the radius of the bore of the bearing, while c is the eccentricity factor for the journal running position.

For graphical integration of eq. 48 see Fig. 23. When $dP/d\theta$ is made the ordinate and θ the abscissa, the area under the curve, for a given set of constants, when integrated from

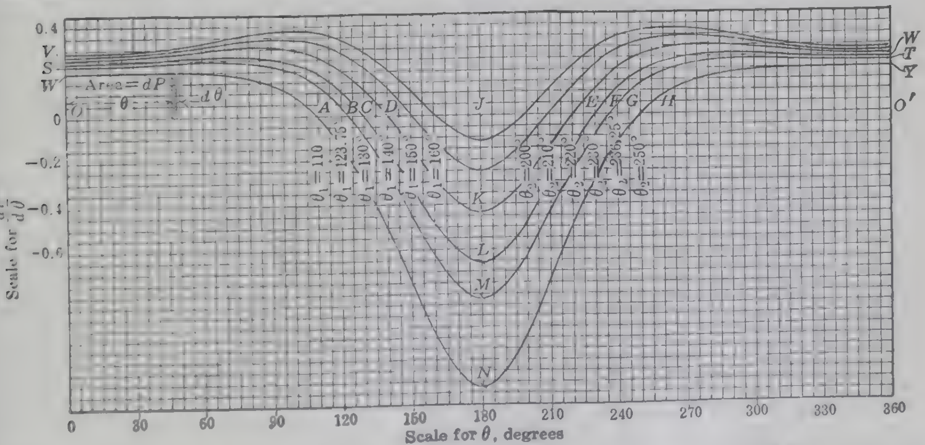

FIG. 23. Graph of eq. 48, assuming $\frac{6\mu Ua}{\eta^2} = 1$ and $c = 0.4$. (H. A. S. Howarth, *ASME Trans.*, Ref. 11)

$\theta = 0°$ to $\theta = 30°$, will be a measure of the pressure in the film at 30°, and so on. It will be noted that the curves and scales are based on the assumption that $c = 0.4$ and $(6\mu Ua)/\eta^2 = 1$. Several values of θ_1 are assumed, and a curve is drawn for each. For only one such curve, $\theta_1 = 123.75$, do the areas under the curve and above the axis of abscissas OO' equal the area under it. Hence in 360° or full bearings, when $\theta_1 = 123.75°$ and $c = 0.4$, the pressure within the film begins at 0 (zero) when $\theta = 0°$, reaches a positive maximum when $\theta = 123.75°$, reaches zero again when $\theta = 180°$, passes to a negative minimum which it reaches at 236.25°, and then rises to become zero again when $\theta = 360°$.

It can readily be understood how integrations between other limits can be made to suit the film conditions existing at the limits, whether they are alike or different. For example, the bearing film might be much less than 360° in extent, and the initial pressure might be well above atmospheric, due to impact, while the final pressure might be atmospheric. For a full description of this graphical process see Ref. 11.

Over-center Running of Journals in Bearings. "Over-center" or "above-center" running is possible, under Reynolds' theory, and is characteristic of bearings whose leading film angle considerably exceeds the trailing film angle. (See Ref. 13.)

A way to prevent the undue rise of the journal, suggested by Howarth, is by offsetting a cap under which a similar counter-acting film will automatically develop. This cap may be mounted with freedom to develop automatically the restraining film, or it may be fixed in a suitable offset position. This method may be used whether the bearing has running clearance or is of the fitted type.

OIL-FILM INSTABILITY. Under certain conditions a phenomenon known as oil-film whirl may occur in journal bearings. According to B. L. Newkirk (Ref. 14):

> The oil film whirl arises from a potential instability of the oil film which supports a rotating journal. It ordinarily develops into whirling or vibration in co-operation with elastic action of the rotor, elasticity of the supporting structure being also a factor. The development of the whirl from a state of steady running seems to occur as follows. A slight shock causes the rotor to vibrate at its natural frequency, which is numerically equal to the critical or resonant speed. This vibration of the rotor causes periodic displacement of the journal from its equilibrium position on the oil film. When the journal is thus displaced the restoring force that develops in the oil film is not directed exactly toward the equilibrium position. There is a component of the restoring force which sets up a forward whirl of the journal about its equilibrium position. If the speed of the rotor is equal to or greater than some value which is approximately twice the whirl frequency the whirl builds up, otherwise it dies out. The whirl occurs at a resonant frequency of the rotor (usually the lowest resonant frequency) for all speeds of rotation above the lowest speed at which whirling develops.

Whirling is preventable by proper design of oil-film bearings that operate at high speed, as by a combination plain and pivoted-shoe bearing for each journal. See also the preceding discussion of over-center running, which is cured in a similar manner, and Ref. 15.

2. LOADING AND FRICTION CHARTS AND TABLES FOR JOURNAL BEARINGS

The charts, tables, and examples that follow are placed in two groups: (1) general characteristics, and (2) optimum characteristics. The classes of bearings covered are lettered A, B, C, D, E, and F. (See Table 2.)

Table 2. Key to Journal Bearing Charts and Tables

Class	Description	Examined by	Characteristics Determined	Data Given in	
				Tables	Figures
A	Eccentrically loaded clearance bearing	Kingsbury	Two optima	3, 4	31–34
B	Eccentrically loaded fitted bearing	Kingsbury	Two optima	5, 6	35–38
C	Centrally loaded clearance bearing	Kingsbury	Two optima	7, 8	39–42
C	Centrally loaded clearance bearing	Howarth	General		24
D	Eccentrically loaded (offset) clearance bearing	Howarth	General		25, 26
E	Eccentrically loaded fitted bearing	Howarth	General		27
F	Full (360°) clearance bearing	Howarth	General		28
All classes of 120° clearance bearing		Howarth	General		29
120°	Centrally loaded clearance bearing	Kingsbury	General		30
120°	Centrally loaded clearance bearing	Kingsbury	Three optima		30

NOTATION

In the discussion which follows, the significance of the symbols used is given below. Unless otherwise specified in the text, all linear dimensions are in inches, and forces (loads) are in pounds.

a = radius of journal.

A = least angle from line of centers to leading edge of partial bearing, measured in direction of rotation. See exception in study of fitted bearings (Fig. 35).

b = width of bearing surface measured along the shaft axis in a journal bearing or, in general, at right angles to direction of motion.

c = eccentricity factor. When multiplied by the radial clearance η, the product $c\eta$ equals distance from center of bearing to center of journal.

F = total tangential friction force at surface of a journal, or at mean diameter of a thrust bearing, per unit of width of bearing surface.

F_1 = correction factor for friction, *with side leakage*.

h = film thickness at any angular position θ in journal bearings, or any distance x for flat tapered film. For fitted journal bearings $h = \epsilon \sin \theta$, and for clearance journal bearings $h = \eta(1 + c \cos \theta)$.

h_0 = minimum thickness of oil film in a bearing, usually. When the line of centers for a clearance bearing does not intersect the partial bearing surface, h_0 is measured where the bearing surface, if extended, would cross that line.

h_1 = thickness of oil film at region of maximum pressure.

h_A = thickness of oil film at entering edge of bearing film, if less than h_m.

h_E = film thickness at trailing edge of partial clearance bearing, when greater or less than h_0.

h_m = maximum thickness of oil film.

H = horsepower friction developed by a journal bearing, or thrust bearing, per unit of bearing width.

Hp = horsepower.

l = length of a bearing face in the direction of motion. In a partial journal bearing, whose angular extent β is expressed in degrees, $l = \pi\beta a/180$. This is useful for determining length-width ratio, l/b, used in selecting side leakage correction factors.

L_1 = correction factor for load carrying capacity, *with side leakage*.

N = revolutions per minute.

n = number of pivoted segments in a thrust bearing.

O = center of curvature of journal when running on oil film.

O' = center of curvature of bearing surface supporting journal.

P = pressure within the oil film where the thickness is h.

p_0 = nominal mean pressure acting on bearing. In journal bearings, p_0 is found by dividing total applied load by (journal diameter × axial bearing width), except where otherwise stated. It also is expressed by $W/2a$. W is taken per unit of width. In thrust bearings, $p_0 = R/nlb$.

P_m or $P_{\max}$ = maximum pressure within oil film of a bearing.

R = total load applied by a journal to a bearing, or by a collar to a thrust bearing, except where otherwise stated.

R' = total reaction of bearing against the journal.

s = a film form dimension (see Figs. 7 and 17).

U = relative velocity of the bearing surfaces (usually inches per second). In thrust bearings it is measured on the mean diameter.

V = relative velocity of bearing surfaces, feet per minute.

w = nominal mean unit load a bearing would carry if side leakage could be neglected. See p_0. The relation is $p_0 = L_1 w$.

W = actual load applied by a journal to its bearing, per unit of axial width = R/b.

Z = character expressing viscosity coefficient in centipoises. See μ.

α = leading angle for partial bearing, measured in direction of motion of journal from leading edge of bearing to line of action of load.

β = angular extent of bearing surface over which perfect film lubrication is maintained. Usually expressed in degrees.

ϵ = eccentricity of journal axis when running in a fitted bearing.

η = radial clearance provided in a clearance bearing. When a = journal radius, $(a + \eta)$ = radius of curvature of a bearing surface, and $c\eta$ = eccentricity of running position of journal axis in a clearance bearing.

θ = angle from reference diameter to point within oil film where thickness is h.

θ_1 = angle θ corresponding with location of maximum unit pressure within the oil film.

λ = coefficient of friction for journal surface. In thrust bearings, λ is the coefficient for mean diameter of thrust collar face. $\lambda = (F_1/L_1)\lambda_H$.

λ' = coefficient of friction for bearing surface.

λ_H = uncorrected coefficient of journal friction in charts.

μ = coefficient of viscosity. When not otherwise specified, μ is expressed in pound-seconds per square inch (Reyns). The term *Reyn* is applied to the coefficient when expressed in English units. The cgs unit for μ is the *Poise* measured in dyne-seconds per square centimeter. One poise = 0.0000145 Reyn; 1 Reyn = 69,000 poises.

ϕ = angle relating load line to line of centers of journal and bearing in Kingsbury's optimum condition. See also bearing cross sections (Figs. 31, 35, and 39).

ϕ_H = angle relating load line to line of centers of journal and bearing in bearing cross sections in Figs. 24 to 29.

GENERAL CHARACTERISTICS OF JOURNAL BEARINGS. General characteristics mean the relations between load-carrying capacity, and also friction, and the operating position of the journal upon the bearing film, shown by the eccentricity factor c in clearance bearings, for a wide range of eccentricities or running positions of the journal.

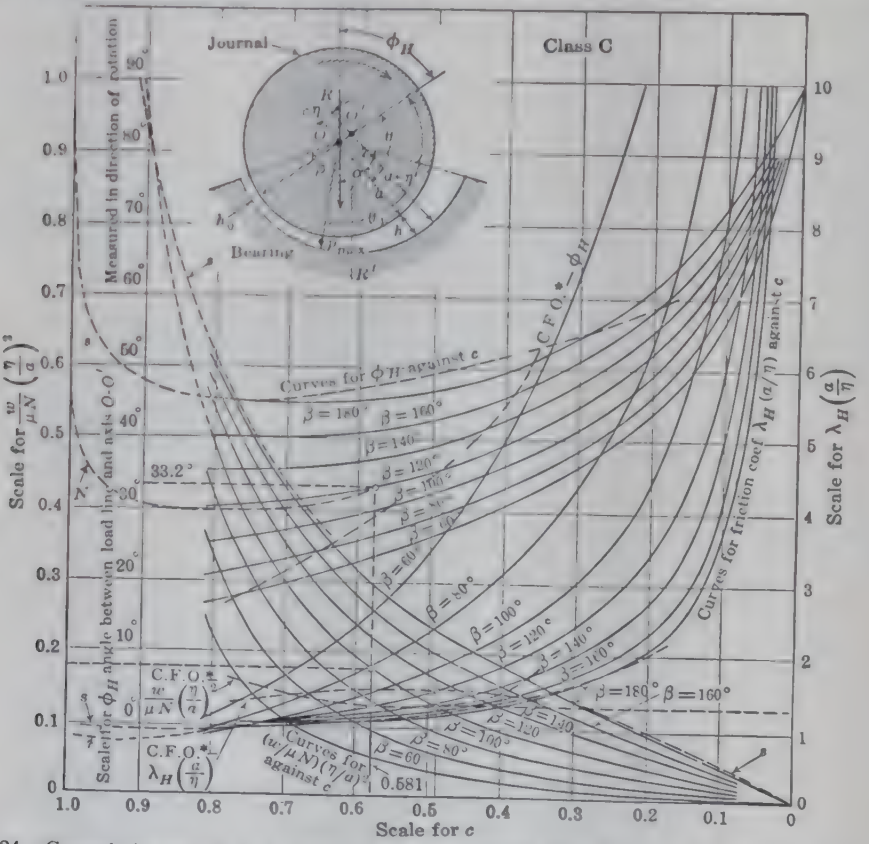

FIG. 24. General characteristics of centrally loaded clearance bearings, Class C, assuming constant velocity and no side leakage. C.F.O.* = Class C friction optima. Where the dotted curves cut the corresponding full line curves the values are identical with the optimum conditions for minimum friction coefficient in Figs. 40 and 41 and Table 8. (H. A. S. Howarth, *ASME Trans.*, MSP-57-2, 1935)

Class C. Centrally Loaded Partial Bearings with Clearance. The general characteristics of these bearings are given in Fig. 24, in which there is also a cross section of the journal and the bearing. Data are given for bearing film arcs ranging from 60° to 180°, covering the load group $(w/\mu N)(\eta/a)^2$, the friction group $\lambda_H(a/\eta)$, and the angular position ϕ_H of the line through the centers of the journal and the bearing, all with relation to the eccentricity factor c, which varies from near zero to about 0.8 (80%). Some data extend to $c = 1.0$. The full lines are those obtained by Howarth, using graphical integration. The dotted curves S are based on Sommerfeld's calculations. Those marked N are based upon Needs' (Ref. 12) calculations. The dotted curves, marked C.F.O., are plotted from data in Kingsbury's table of optimum friction coefficient condition of operation (Table 8).

In this case there is one such optimum eccentricity factor c for each film angle. This chart (Fig. 24) is one of the most complete and the most useful available.

The side leakage correction factors can be applied to the ordinates of the curves of this chart in the manner already explained. The symbol w that appears in the capacity group is intended to convey the fact that the ordinates of the capacity curves are uncorrected for side leakage. As the character p_0 is ordinarily thought of as being the actual pressure due to applied load, the relationship $p_0 = L_1 w$ would hold and w can be determined from it. By this means the eccentricity of operation can be determined. Once that value of c is known, it must be held and the corresponding values of the other symbol groups found. When they are so found the correction factors may be applied to their ordinates. Thus, applying L_1 to p_0, we find $w = (p_0/L_1)$. Entering the chart with the symbol group $(w/\mu N)(\eta/a)^2$, we find the ordinate of the proper curve leads us to the base scale, where we find and read the value of c. Holding this value, we extend the ordinate to the friction coefficient symbol group curve. Then we read the value of that new ordinate on the $\lambda_H(a/\eta)$ scale. Then we place the correction factor F_1/L_1 before the ordinate value and find the true value of $\lambda_H(a/\eta)$.

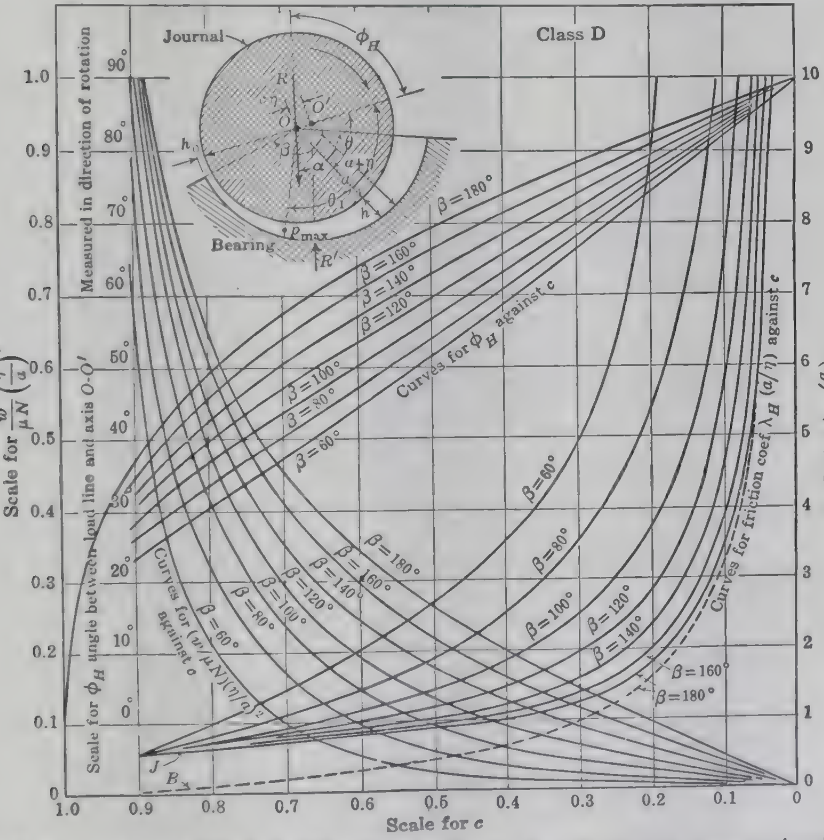

FIG. 25. General characteristics of offset clearance bearings, Class D, assuming constant viscosity and no side leakage. See Fig. 26 for corresponding ratios of α/β. This class of bearings differs somewhat from the eccentrically loaded bearings in Class A. (H. A. S. Howarth, *ASME Trans.*, MSP-57-2, 1935)

EXAMPLE 1. Given a centrally loaded 120° bearing with a total load $R = 10{,}000$ lb and actual nominal pressure $p_0 = 125$ psi. Journal diameter is 8 in., and bearing width is 10 in. Clearance ratio $\eta/a = 0.001$, and speed $N = 400$ rpm. Determine the running position of the journal when using two oils of viscosity coefficient $\mu = 3.4 \times 10^{-6}$ Reyn, and 10.2×10^{-6} Reyn, respectively.

Solution. In Fig. 24 the scale at the left represents a symbol group in which all values are known except w, which is the ideal nominal unit pressure that the bearing would sustain if side leakage could be neglected. This ideal pressure is reduced to actual pressure p_0 by side leakage, and $p_0 = L_1 w$. Correction factor L_1 is found from Fig. 18. The ratio $l/b = [(120/360)\pi 8]/10 = 0.839$. When Fig. 18

is entered at $l/b = 0.839$, the correction factors are found to be: $L_1 = 0.51$; $L_1/F_1 = 0.555$; $F_1 = 0.92$. Then $W = 125/0.51 = 245$, and

$$\left(\frac{w}{\mu N}\right)\left(\frac{\eta}{a}\right)^2 = \frac{245 \times 1 \times 10^{-6}}{\mu \times 400} = \frac{0.613 \times 10^{-6}}{\mu}$$

The next step is to substitute in the above expression the two values of μ given in the statement of the problem, and with the resulting values enter Fig. 24 at the left. First substituting $\mu = 3.4 \times 10^{-6}$, $(w/\mu N)(\eta/a)^2 = 0.180$. Locating this point on the load capacity curve, $\beta = 120°$ (the group of curves starting at the lower right), find $e = 0.581$. The ordinate of $e = 0.581$ intersects the friction coefficient curve for $\beta = 120°$ (group of curves starting at the lower left) at $\lambda_H a/\eta = 1.29$. This ordinate also intersects the ϕ_H curve (group of curves starting at the upper right) for $\beta = 120°$ at $\phi_H = 33.2°$.

The actual friction coefficient will be $\lambda = (F_1/L_1)\lambda_H = 1.29 \times 10^{-3}/0.555 = 0.00233$.

The journal running position will be on the line $\phi_H = 33.2°$, and its distance from the center of the bearing will be $ea = 0.581 \times (8/2) \times 0.001 = 0.002324$ in. The minimum film thickness will be $h_0 = (1 - e)a = 0.001676$ in. Optimum eccentricity is shown by the dotted C.F.O. loading curve $(w/\mu N)(\eta/a)^2$ to be 0.49 for a 120° bearing, with a corresponding value of $h_0 = 0.00204$. Hence, with $\mu = 3.4 \times 10^{-6}$, this bearing is not quite so safe as the optimum would be.

Solving the problem with $\mu = 10.2 \times 10^{-6}$, the value of $(w/\mu N)(\eta/a)^2$ for entering the chart is 0.060. The following values then are established:

$$e = 0.28; \quad \phi_H = 46°; \quad \lambda_H \frac{a}{\eta} = 2.54; \quad \lambda = 0.00458; \quad h_0 = 0.00288$$

Friction and minimum film thickness are greater with the heavier oil. An intermediate oil would cause the journal to run with optimum eccentricity. The decision then rests on which of the three oil film thicknesses $h_0 = 0.00168$, 0.00204, or 0.00288 in. best suits the required shaft alignment and other conditions. Heavier oil is best where shaft alignment conditions are not ideal.

Class D. Eccentrically Loaded (Offset) Partial Bearings with Clearance. This series is somewhat different from Kingsbury's optimum eccentrically loaded bearings. However, it must be remembered that in Kingsbury's tables only one eccentricity is given as optimum whereas in Fig. 25, by Howarth, the characteristics of each bearing angle are given for eccentricities ranging from zero to 0.9 (90%). One thing to note about this series is that the leading angle varies with the eccentricity for a given total film angle. This is seen in Fig. 26.

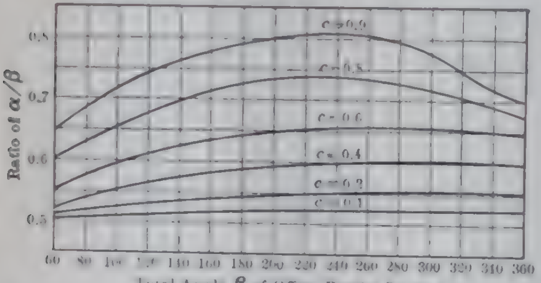

FIG. 26. α/β Values of Class D journal bearings. For other characteristics, see Fig. 25. (H. A. S. Howarth, *ASME Trans.*, MSP-57-2, 1935)

Howarth thought that this Class D series was close to the optimum, although he did not seek an exactly optimum one. How close it came to Kingsbury's later determined optima may be seen in Fig. 29, which will be discussed later.

When solving problems in this series proceed as for Class C Example 1 until the eccentricity is determined. Then pass from Fig. 25 to 26 and find the α/β ratio for that eccentricity, entering of course with β.

Class E. Fitted Partial Bearings. This is definitely an eccentrically loaded series. A fitted bearing has its greatest capacity at about 120° film angle. Howarth gives the capacities from 60° to 120°. Kingsbury in his optima gives the capacity also for 150° and shows that it is definitely less than for 120°. Kingsbury's and Howarth's values differ only slightly. The Kingsbury values for optimum friction coefficient are shown by dotted lines on Howarth's chart (Fig. 27).

EXAMPLE 2. Given a 100° fitted bearing of journal diameter 5 in., and width 6 in., carrying a total load R of 3000 lb, running at $N = 300$ rpm, and using oil of viscosity $\mu = 3 \times 10^{-6}$ Reyn. Find the minimum film thickness.

Solution. $l/b = (5\pi/6) \times (100/360) = 0.727$, from which (see Fig. 18) $L_1 = 0.565$, and $w = 3000/(6 \times 5 \times 0.565) = 177$. Then $(w/\mu N) \times 10^{-6} = (177 \times 10^{-6})/(3 \times 10^{-6} \times 300) = 0.197$, which value is used to enter Fig. 27. The intersection of this value with the lower diagonal $\beta = 100$ gives a value of ϵ/a of 0.0008. The minimum thickness of oil film h_0 will be at the trailing edge of the bearing and is, numerically, $h_0 = \epsilon \sin \theta$. From inset in Fig. 27, $\theta = 270° + \beta - (\phi_H + \alpha) = 157.6°$. Hence $h_0 = 0.0008 \times 2.5 \times 0.381 = 0.00076$.

Other data that may be obtained from Fig. 27 are: uncorrected coefficient of friction $\lambda_H = 0.00082$. Applying correction factor $L_1/F_1 = 0.61$ (Fig. 18), the actual coefficient of friction

$$\lambda = \frac{\lambda_H}{L_1/F_1} = \frac{0.00082}{0.61} = 0.00134$$

Class F. Full (360°) Bearings with Running Clearance. This bearing, which is shown in the inset in Fig. 28, is treated as a half bearing so far as carrying capacity and running position are concerned. As regards friction, it is treated as a full bearing in which the running position of the journal is the same as for a half bearing. The line of application of the load when the film is in running position would not pass through the center of the supporting film arc. The useful film of the bearing, therefore, may be treated as that of an offset bearing, Class D. In Fig. 28, the load capacity curve is taken from Fig. 25 for $\beta = 180°$, Class D bearings. The pressure film in full bearings is not likely to exceed 180° in angular extent. The experiments of Stanton (Ref. 16), Bradford (Ref. 17), and McKee (Ref. 18) indicate shorter films for certain conditions. For other arcs than 180° the appropriate curve for load capacity in Fig. 25 can be used to find the eccentricity. Figure 28 then can be entered with the eccentricity so found, the approximate total friction determined, and the horsepower loss estimated. The friction coefficient curve in Fig. 28 can be used only with the load capacity curve in the same illustration. Example 3 shows the use of side leakage correction factors in a full bearing.

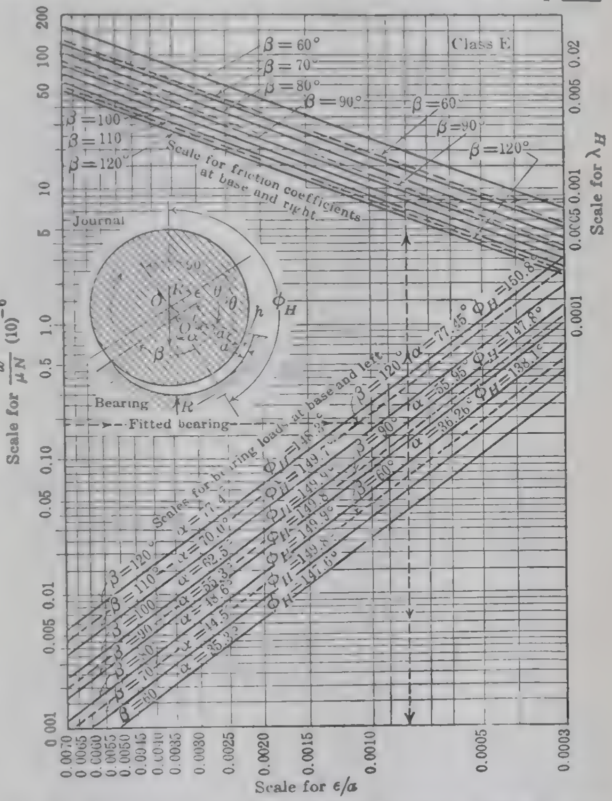

FIG. 27. General characteristics of fitted bearings, Class E. This series differs slightly from Class B as indicated by the broken lines for $\beta = 60°$, $\beta = 90°$, and $\beta = 120°$, which represent the optima for minimum friction coefficient. (H. A. S. Howarth, *ASME Trans.*, MSP-57-2, 1935)

EXAMPLE 3. Determine the friction power loss and friction coefficient of a full bearing of diameter $2a = 4$ in., width $b = 8$ in., running at $N = 3600$ rpm, and carrying a total journal load $R = 3600$ lb. The clearance ratio $\eta/a = 0.003$, and the oil viscosity $\mu = 2 \times 10^{-6}$ Reyn.

Solution. In order to find L_1, assume $\beta = 180°$. Then $l/b = (4\pi/8) \times (180/360) = 0.79$, and from Fig. 18 $L_1 = 0.53$. $F_1 = 0.925$, and $L_1/F_1 = 0.575$.

$$w = \frac{R}{2a \times b \times L_1} = \frac{3600}{4 \times 8 \times 0.53} = 212 \text{ psi}$$

Figure 28 is entered with the value of the symbol group

$$\left(\frac{w}{\mu N}\right)\left(\frac{\eta}{a}\right)^2 = \frac{212 \times 9 \times 10^{-6}}{2 \times 10^{-6} \times 3600} = 0.265$$

This value on the load capacity curve corresponds to a value of eccentricity factor $c = 0.5$. For this value of c the value of $\lambda_H a/\eta$ is read from the friction coefficient curve as 1.88. The total friction factor is read from the total friction curve as 3.2.

$$\text{Total power loss} = \text{Total friction factor} \times \left(\frac{\mu b}{2}\right)\left(\frac{a}{\eta}\right) a^2 F_1 N^2 \times 10^{-5} = 4.1 \text{ hp}$$

$$\text{Actual coefficient of friction } \lambda = \frac{\lambda_H}{L_1/F_1} = \frac{\lambda_H}{0.583} = 0.0098$$

If λ_H is checked back to the total power loss, the latter is found to be the same if the correction factor is properly introduced in $\lambda = (F_1/L_1)\lambda_H$.

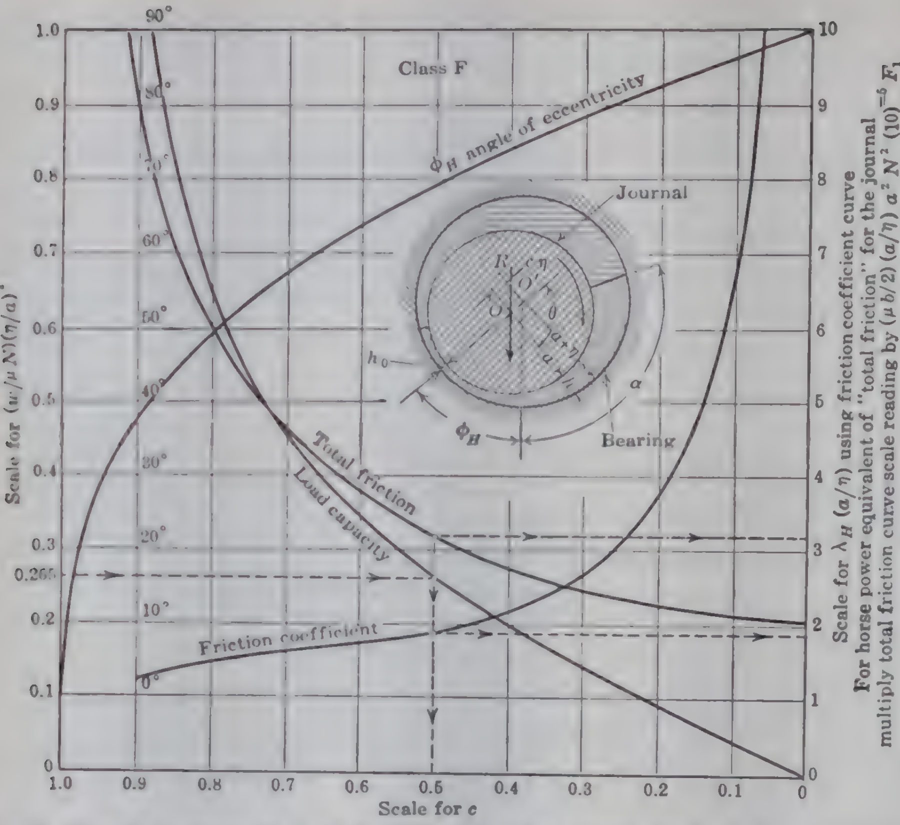

FIG. 28. General characteristics of full bearings, Class F, with running clearance, assuming constant viscosity and no side leakage. The load capacity curve corresponds to that for an offset (Class D) bearing for which $\beta = 180°$. The friction curves assume that for the purpose of calculating this loss the bearing film may be considered as extending all around the journal. This assumption is arbitrary but appears to be well on the safe side. (H. A. S. Howarth, *ASME Trans.*, MSP-57-2, 1935)

All Classes of 120° Partial Bearings with Clearance. In Fig. 29 the general carrying capacity characteristics of this common bearing film angle are given more fully than for any other angle. As heretofore stated this investigation was made to find out whether a journal center would rise above the bearing center under any condition, when the load acts directly downward. Such over-center running was found to be possible and also preventable. (See Ref. 13.)

Aside from its original purpose, Fig. 29 shows many other things about oil film bearings. For example, it shows the conditions under which negative pressure may be expected at the trailing end of a film and also when it may be looked for at the leading end.

If a line is drawn through the abscissa peaks of the eccentricity factor c curves, it will pass through the point marked ALO. That mark means "Class A load optimum" as determined by Kingsbury for a 120° Class A clearance bearing.

The dot and dash line marked "offset series, variable α/β" describes the 120° bearing of Howarth's offset series of clearance bearings, Class D. (See Figs. 25 and 26.) It was said above in connection therewith that Kingsbury's optimum "points" were not far from the "offset series." Note where those points ALO and AFO lie in Fig. 29 with respect to the "offset series" line.

The CLO and CFO points are, as expected, on the curve for which $\alpha/\beta = 0.5$ (by definition). Figure 29 also gives the angular location, θ_1, of the maximum film pressure. These curves may be used to determine whether there is a possibility of negative pressures existing in the oil film. All pressures in the film are positive between the lines M and N. An unpublished investigation by S. J. Needs shows that negative pressure is to be expected in a finite bearing where the bearing of infinite width would show all pressures to be positive. Hence, when the data of a problem show that the running position approaches the upper limit line of Fig. 29, some negative pressure is probable. If such conditions exist, it is advisable to place the problem in some other class of bearing, using $\alpha = 60°$ as suggested below.

If conditions of operation are such that negative pressures may occur at the trailing end, 120° bearings are best studied as if they were Class A, eccentrically loaded bearings, or Class D, offset bearings with $\beta < 120°$. In both cases, leading angle α should be taken as 60°, allowing the trailing angle $(\beta - \alpha)$ to be determined by the data in the class used.

EXAMPLE 1. Determine whether negative pressure would exist in a journal of diameter $2a = 6$ in., and width $b = 10$ in., carrying a total load $R = 600$ lb at $N = 1000$ rpm, taking α/β ratios as follows: (1) $\alpha/\beta = 0.44$; (2) $\alpha/\beta = 0.52$; (3) $\alpha/\beta = 0.62$. Clearance ratio $\eta/a = 0.002$, and the oil viscosity $\mu = 4.0 \times 10^{-6}$ Reyn.

Solution. Determine correction factor L_1 corresponding to $l/b = (6\pi/10) \times (120/360) = 0.628$. From Fig. 18, $L_1 = 0.613$, and $w = 600/(6 \times 10 \times 0.613) = 16.30$. Since $\mu = 4.0 \times 10^{-6}$, the group

$$\left(\frac{w}{\mu N}\right)\left(\frac{\eta}{a}\right)^2 = \frac{16.3}{4 \times 10^{-6} \times 1000} \times 0.002^2 = 0.0163$$

If an ordinate is erected at 0.0163 on the scale $(w/\mu N)(\eta/a)^2$ in Fig. 29 it will intersect the curves for $\alpha/\beta = 0.44$, 0.52, and 0.62 at the points 1, 2, and 3 respectively. Hence, with ratios of α/β of 0.44 and 0.62, negative pressure is quite likely to exist at the trailing and leading ends, respectively, of the bearing. With a ratio of $\alpha/\beta = 0.52$, the bearing probably will not have negative pressure.

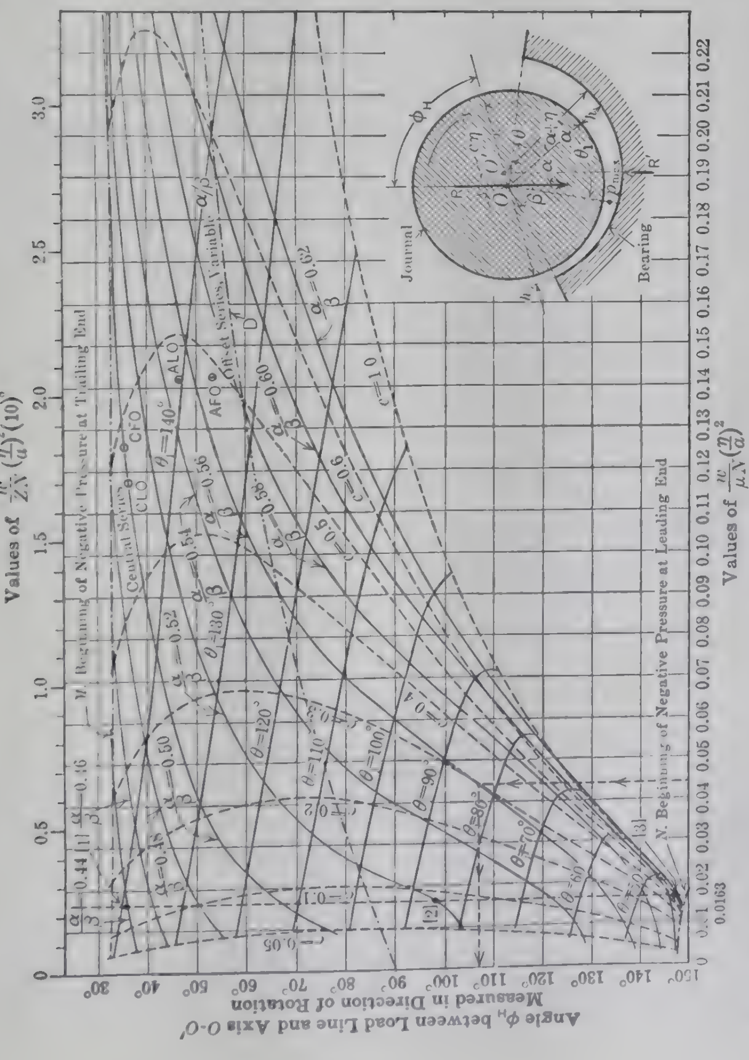

FIG. 29. General capacity characteristics of 120° clearance bearings, including Classes A, C, and D, assuming constant viscosity and no side leakage. Angular length of bearing $\beta = 120°$. (H. A. S. Howarth, *ASME Trans.*, MSP-57-2, 1935)

Other items that may be determined from Fig. 29 are the total lift of the journal and the point of maximum pressure in the oil film.

EXAMPLE 5. Determine the lift of the journal when in running position, and the point of maximum pressure in the oil film of a centrally loaded, type Class C, 120° clearance turbine bearing without a cap, with ratio of $\alpha/\beta = 0.56$, journal diameter $2a = 15$ in., length $b = 30$ in.; vertical load $R = 67{,}500$ lb., speed $N = 1500$ rpm. Clearance ratio $\eta/a = 0.001$ in. The oil at operating temperature has a viscosity $\mu = 3.4 \times 10^{-6}$ Reyn.

Solution. Ratio $l/b = (15\pi/30) \times (120/360) = 0.524$, whence from Fig. 18, $L_1 = 0.673$.

$$w = \frac{R}{2a \times b \times L_1} = \frac{67{,}500}{15 \times 30 \times 0.673} = 223$$

$$\left(\frac{w}{\mu N}\right)\left(\frac{\eta}{a}\right)^2 = \frac{223}{3.4 \times 10^{-6} \times 1500} \times 0.001^2 = 0.0437$$

with which value Fig. 29 is entered. The ordinate erected at $(w/\mu N)(\eta/a)^2 = 0.0437$ intersects the curve $\alpha/\beta = 0.56$ at $\phi_H = 107°$, which corresponds to a value of $c = 0.3$.

$$\text{Lift} = \eta(1 - c \cos \phi_H) = 0.075[1 - \{0.3 \times (-0.29237)\}] = 0.0684 \text{ in.}$$

The point of maximum pressure P_m is the value of θ at the point where the ordinate $(w/\mu N)(\eta/a)^2 = 0.0437$ intersects the curve $\alpha/\beta = 0.56$, which is $\theta_c = 83°$. P_m, therefore, will be on the radius of the journal in running position 83° in the direction of rotation from the line $O - O'$ joining the center of the journal and the center of curvature of the bearing.

Optima and Deviations for a 120° Class C Journal Bearing. Just as Fig. 20 was applied to the study of optimum conditions for flat-wedge films, so may Fig. 30 be applied to the finding of the optima for the curved wedge of a 120° journal bearing of the centrally loaded clearance type (Class C). The scale for M needs to have a somewhat different but parallel meaning because of the curvatures and the fact that the least thickness h_0 does not necessarily lie at the terminus of the film.

It is seen in Fig. 30, as it was in Fig. 20, that the value of M is different for the three separate optima. See points of maxima and minima of curves 1, 2, and 3.

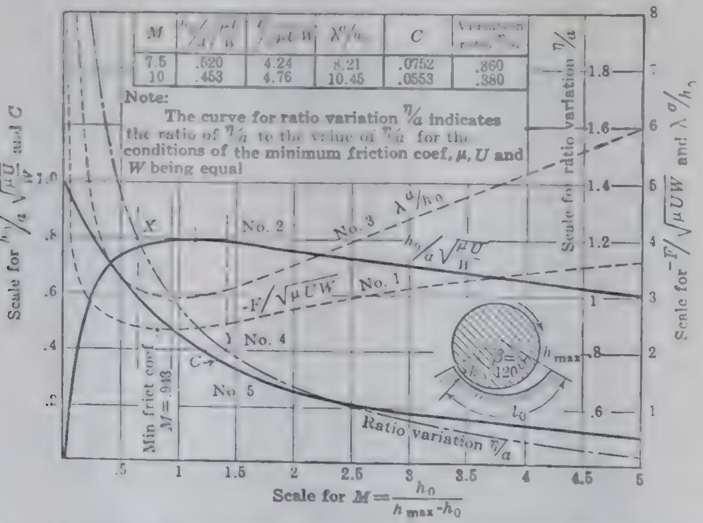

FIG. 30. Effect of deviation from optimum friction-coefficient conditions in a 120° centrally loaded (Class C) clearance bearing. This chart is comparable with Fig. 20 for flat bearing faces. (H. A. S. Howarth, *ASME Trans.*, MSP-57-2, 1935)

The data contained in Kingsbury's tables of optimum conditions that are to follow were determined from points of inflection like the above for curves 2 (maximum capacity for a given minimum thickness h_0) and 3 (least friction coefficient for a given minimum thickness h_0).

Many series of clearance journal bearing films are possible. In the present study the film of Fig. 30 is a curved wedge, extending from $h_{\max}$ at the entering edge to and beyond

h_0, where the film thickness is least, for which the wedge length is l_0. Length l_0 usually will be a little less than 120°, depending on operating conditions. The length l_0 would equal the film length l when h_0 lies at the end of the film.

The series of curves, showing the relations of dimensionless groups, will be useful in arranging tolerances for journal and bearing diameters. The curves that are plotted against a scale of $M = h_0/(h_{\max} - h_0)$ are: (1) Friction drag $= -F/\sqrt{\mu U W}$. (2) Bearing capacity, $h_0/a\sqrt{(\mu U/W)}$. (3) Friction coefficient, $\lambda(a/h_0)$. (4) Clearance ratio η/a. (5) Eccentricity factor, c. (See pp. 12-14 to 12-16 for notation.) The application of the curves can be illustrated by an example.

Example 6. Determine the effect of an increase of 20% and a decrease of 20% in clearance ratio from optimum for optimum friction condition of a 120° clearance bearing.

Solution. Minimum friction coefficient ratio is shown by curve 3 to correspond to a value of $M = 0.943$. Optimum clearance ratio η/a corresponding to this has been taken as unity in plotting curve 4. An increase of 20% corresponds to point X on curve 4 with a corresponding value of $M = 0.65$. The ordinate through X intersects the other curves to give the following values: friction drag, curve 1, 2.4; bearing capacity, curve 2, 0.773; friction coefficient, curve 3, 3.1; eccentricity factor, curve 5, 0.587.

A decrease of 20% in clearance ratio (η/a) corresponds to the point Y on curve 4, with a corresponding value of $M = 1.42$. From the intersection of this ordinate with the several curves, the following values are found: Friction drag, 2.53; bearing capacity, 0.788; friction coefficient ratio, 3.1; eccentricity factor, 0.348.

The tabulation at the top of Fig. 30 permits the extension of the curves beyond the limits of the chart. With a value of $M = 10$, the other values are such that an accurately made, properly designed bearing would function with pure film lubrication.

OPTIMUM CHARTS AND TABLES FOR JOURNAL BEARINGS. The charts, tables, and figures that follow are given for two of the three sets of optimum operating conditions that were discussed in connection with Fig. 30 for curved-wedge films and with Fig. 20 for flat-wedge films. In each of those figures curve 2 showed the maximum load conditions and curve 3 those for minimum friction coefficient, both with relation to a chosen minimum film thickness h_0 and a film length. For the flat wedge the length appears directly as l, but for the curved wedge it usually appears indirectly as the film arc β and the journal radius a.

As side leakage factors enter into the examples that follow and also into Figs. 34, 38, and 42, they should be applied as explained below. If this influence be neglected in the solution of bearing problems, the data of the charts will not agree well with actual conditions, and side leakage factors, therefore, must be included in the bearing problem data. Figure 18 gives factors applying to optimum film proportions, but they are fairly dependable when applied to conditions not too far different from optimum. These are the best generally applicable data available for side leakage corrections. When applied to abnormal conditions, they tend to bring results toward correct values, and usually are on the safe side.

Figure 18 is used as follows: In the dynamical tables and curves following which apply to the various classes of bearings, as enumerated above, numerical coefficients are for infinitely wide conditions, under which side leakage is zero. For bearings of finite width and a given ratio of (length/width) the numerical coefficients are to be multiplied by a correction factor from Fig. 18. The proper correction curve in Fig. 18 to use for the various symbols or symbol groups of the dynamical tables and curves is:

Symbol group	W	F	λ or $\dfrac{F}{W}$	H	$\dfrac{H}{W}$	$\dfrac{W}{H}$	$\dfrac{\lambda}{\sqrt{\mu N/p_0}}$
Correction factor	L_1	F_1	$\dfrac{F_1}{L_1}$	F_1	$\dfrac{F_1}{L_1}$	$\dfrac{L_1}{F_1}$	$\dfrac{F_1}{\sqrt{L_1}}$

Data given below are useful in the design of optimum bearings of classes A, B, and C, respectively. They show the relation of proportion, dimensions, power loss, film thickness, speed, and load for a variety of conditions with each type. Total load R on the bearing, and speed, usually are the known factors, and the minimum thickness of the oil film h_0 may be assumed. (See examples below.) The permissible loading of the bearing p_0 also may be assumed. The projected area of the bearing then is R/p_0; it also is $2a^2\,(b/a)$. The ratio of width to radius of journal, i.e., b/a, when decided, may be substituted in $2a^2\,(b/a)$. By equating the two expressions for projected area, the value of a can be determined. Then from R and b the value of W is obtained.

Class A. Optima for Eccentrically Loaded Clearance Bearings (Fig. 31). Table 3 gives optimum values for maximum load.

Table 4 and Figs. 32, 33, and 34 give optimum values for minimum friction coefficient.

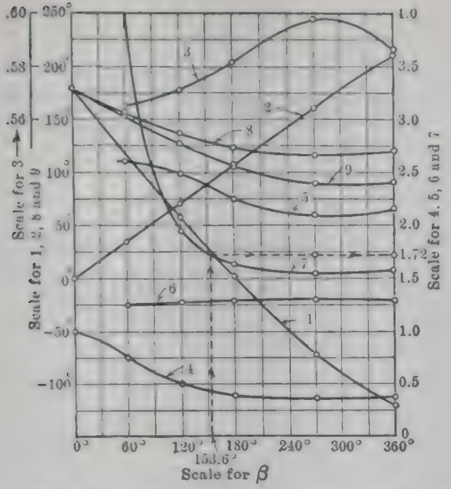

FIG. 32. Geometrical optima for minimum friction coefficient. See Table 4. (Albert Kingsbury, *ASME Trans.*, RP-54-7, 1932)

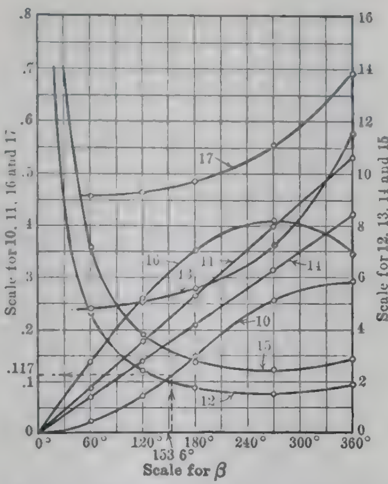

FIG. 33. Dynamical optima for minimum friction coefficient. See Table 4. (Albert Kingsbury, *ASME Trans.*, RP-54-7, 1932)

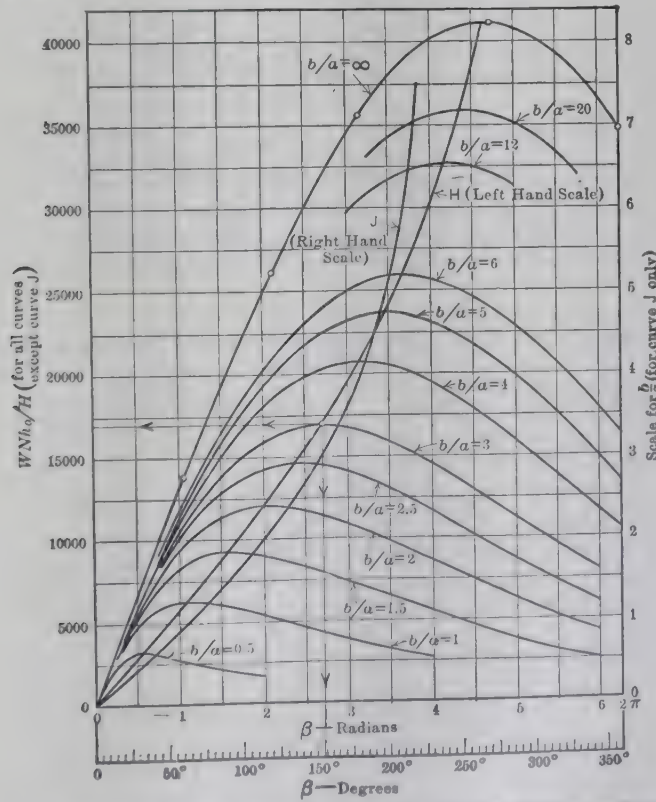

FIG. 34. Side leakage chart for Class A journal bearings for minimum friction coefficient. See Fig. 31.

This chart shows values of nondimensional group (WNh_0/H) as affected by side leakage, with film forms for minimum coefficient of friction. Curve J gives values of b/a at which group (WNh_0/H) is greatest for each value of β. See Figs. 32 and 33 and Tables 3 and 4 for optimum conditions, assuming constant viscosity and no side leakage. When a curve for a given ratio of b/a is chosen, each ordinate of it will be correct for the optimum relation of the symbols in this group. Hence the correction factors for side leakage are already allowed for in the heights of these ordinates. (Albert Kingsbury, *ASME Trans.*, RP-54-7, 1932)

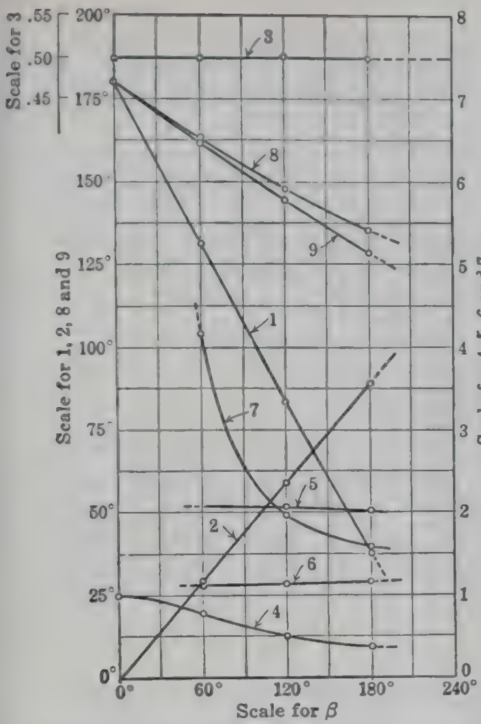

FIG. 40. Geometrical optima for minimum friction coefficient for Class C journal bearings. See Table 8. (Albert Kingsbury, *ASME Trans.*, RP-54-7, 1932)

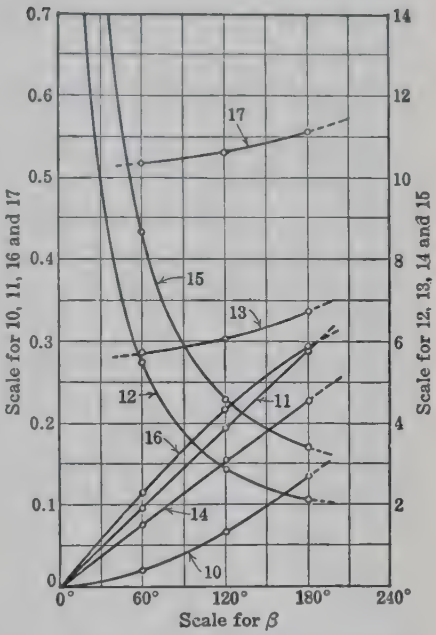

FIG. 41. Dynamical optima for minimum friction coefficient for Class C journal bearings. See Table 8. (Albert Kingsbury, *ASME Trans.*, RP-54-7, 1932)

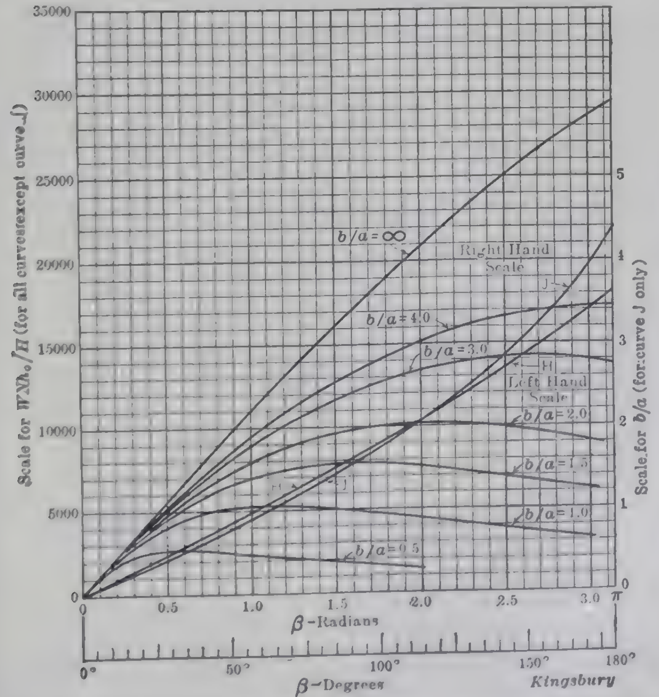

This chart shows the values of the nondimensional group (WNh_0/H) as affected by side leakage with film forms for the minimum coefficient of friction. Curve J gives the value of b/a at which group (WNh_0/H) is greatest for each value of β. See Figs. 40 and 41 and Tables 7 and 8 for optimum conditions, assuming constant viscosity and no side leakage. When the curve for a given ratio of b/a is chosen, each ordinate of it will be correct for the optimum relation of the symbols in this group. Hence the correction factors for side leakage are already allowed for in the heights of those ordinates.

FIG. 42. Side leakage chart for Class C clearance bearings, for minimum friction coefficients. See Fig 39. (Albert Kingsbury, *ASME Trans.*, RP-54-7, 1932)

The radius of curvature of the bearing is greater than that of the journal. The line of application of the load does not pass through the center of the bearing arc, and $\alpha > \beta/2$. The optimum condition for best ratio of α/β for values of β from 0 to 360° are given in Figs. 32 to 34 and Tables 3 and 4. Their use is best shown by an example.

Example 7. Determine the proportions of a bearing of minimum friction to support a load of 25,000 lb at 1500 rpm with $h_0 = 0.003$ in., with a pressure of 200 psi of projected area.

Solution. Projected area = 25,000/200 = 125 sq in. = $2a^2(b/a)$. Assume $b/a = 3$, whence $a = \sqrt{125/6} = 4.564$ in. This value should be checked for strength in bending and in torsion.

From the curve $b/a = 3$ in Fig. 34, the minimum power loss H per unit of width b occurs with a value of $\beta = 153.6° = 2.68$ radians, corresponding to a value of $WNh_0/H = 16{,}900$, whence

$$\text{Total power loss } (H \times b) = 25{,}000 \times 1500 \times \frac{0.003}{16{,}900} = 6.66 \text{ hp}$$

This figure does not include losses in any clearance spaces outside of the arc of contact β.

Clearance η is determined as follows. The ratio of η/h_0 is found from curve 7, Fig. 32, to be 1.72, corresponding to $\beta = 153.6$, when $\eta = 1.72h_0 = 1.72 \times 0.003 = 0.00516$ in.

Bore diameter of bearing = $2(a + \eta) = 2(4.564 + 0.00516) = 9.138$.

Clearance ratio $\eta/a = 0.00516/4.564 = 0.00113$.

To ascertain required oil viscosity coefficient, correction factors must be determined by means of Fig. 18. Arc length of bearing surface $l = \beta$ (radians) $\times a = 2.68 \times 4.564 = 12.23$ in. Width $b = 3a = 3 \times 4.564 = 13.69$, and $l/b = 0.893$. At the points on the several curves in Fig. 18 corresponding to $l/b = 0.893$, the following correction factors are found: $L_1 = 0.487$; $F_1 = 0.916$; $L_1/F_1 = 0.532$. To ascertain the mean viscosity in the oil film, refer to group 10 and curve 10, Table 4 and Fig. 33. For an infinitely wide bearing and $\beta = 153.6$, curve 10 shows the value of $W(h_0^2/\mu Na^3)$ to be 0.117. Applying the correction factor, $W(h_0^2/\mu Na^3)L_1 = 0.117 \times 0.487 = 0.05698$. The actual mean load per unit width of bearing is $W = 25{,}000/13.69 = 1826$ lb. Substituting this and other known values in group 10, we find

$$\mu = \frac{1826 \times 0.003^2}{0.05698 \times 1500 \times 4.564^3} = 2.022 \times 10^{-6} \text{ Reyn}$$

$$= 69{,}000 \times 2.002 \times 10^{-6} = 0.1395 \text{ poise, corresponding to a light machinery oil at 130 to 140 F}$$

For corresponding commercial viscosities, see p. 12-03.

The coefficient of friction λ is found by means of curve 12 and group 12, Fig. 33, and Table 4. Let m = the value on curve 12 corresponding to value of β. In the present case, $\beta = 153.6$, whence $m = 2.00$. Then

$$\lambda = \frac{F_1}{L_1} \times m \times \frac{h_0}{a} = \frac{2.00 \times 0.003}{0.532 \times 4.564} = 0.00247$$

Inspection of Fig. 34 shows that, other things being equal, an increase of the ratio b/a will reduce the relative power loss. (See Example 8.) The possible increase in b/a is limited by considerations of space, cost, and strength or elasticity of the journal. In Example 1, β might be increased, following the curve $b/a = 3$, Fig. 34, to obtain a greater bearing area, with, however, a relatively greater friction loss. Other data for the bearing in question can be found from Figs. 32 and 33, and Tables 3 and 4; for example, leading angle α from group 3 and curve 3.

Example 8. Assume the same data as for Example 7, excepting that $b/a = 4$. Then using the same curves and tables, we have,

$$a = \sqrt{\frac{125}{8}} = 3.953 \text{ in.; } \beta = 180.8° = 3.155 \text{ radians for least power loss}$$

$$\text{Total power loss} = \frac{25{,}000 \times 1500 \times 0.003}{20{,}700} = 5.435 \text{ hp}$$

Clearance $\eta = 1.622h_0 = 0.004866$ in. $= 0.00123$ in. per inch of diameter

Length $l = 3.155 \times 3.953 = 12.47$ in. Width $b = 4 \times 3.953 = 15.81$ in.

Ratio $l/b = 0.789$. This determines the correction factors:

$$L_1 = 0.533;\ F_1 = 0.924;\ \frac{L_1}{F_1} = 0.577$$

$$W = \frac{25{,}000}{15.8} = 1581 \text{ lb}$$

$$\mu = \frac{1581 \times 0.003^2}{0.1517 \times 0.533 \times 1500 \times 3.953^3} = 1.90 \times 10^{-6} \text{ Reyn, corresponding to 0.131 poise}$$

$$\lambda = \frac{F_1}{L_1} \times m \times \frac{h_0}{a} = \frac{1.762 \times 0.003}{0.577 \times 3.953} = 0.002318.$$

The charts and tables also may be used to determine proper radial clearance or oil viscosity for a known set of other conditions. (See Example 9.)

Class B. Optima for Fitted Partial Bearings (Fig. 35). Table 5 gives optimum values for maximum load.

Table 6 and Figs. 36, 37, and 38 give optimum values for minimum friction coefficient.

The journal and bearing have the same radius of curvature. The line of application of the load does not pass through the center of the bearing arc, and $\alpha > \beta/2$. Figures 36 and 37 and Tables 5 and 6 show optimum conditions for values of β from 0 to 150°. The procedure followed in design is the same as that for Class A bearings, except that reference is made to the tables and curves for Class B bearings corresponding to those used for Class A bearings in Examples 7 and 8. (See also Example 2.)

Class C. Optima for Centrally Loaded Clearance Bearings (Fig. 39). Table 7 gives optimum values for maximum load.

Table 8 and Figs. 40, 41, and 42 give optimum values for minimum friction coefficient. The radius of curvature of the bearing is greater than that of the journal. The line of application of the load passes through the center of the bearing arc, and $\alpha = \beta/2$. Figures 40 to 42 and Tables 7 and 8 show optimum conditions for values of β from 0 to 180°. Bearing problems may be solved by the same procedure as used for Examples 7 and 8 except that reference should be made to the curves and tables of Class C bearings. Example 9 shows the application of the curves to the selection of the correct radial clearance η.

EXAMPLE 9. Determine the best radial clearance η for a bearing in which the total load $R = 25{,}000$ lb, $N = 1500$ rpm, $\beta = 120°$, $P_0 = 125$ psi, ratio of width to radius, $b/a = 4$, oil viscosity, $\mu = 3.4 \times 10^{-6}$ Reyn. Bearing is centrally loaded.

Solution. By procedure outlined in Example 7 and from the foregoing data, $2a = 10$ in., $b = 20$ in., $W = 1250$, $l = 10.47$ in., $l/b = 0.524$.

Correction factors from Fig. 18 will be $L_1 = 0.672$, $F_1 = 0.947$, $L_1/F_1 = 0.710$. Then from group 10 in Table 8, by introducing correction factor L_1, we have $Wh_0^2/\mu Na^3 = 0.0672L_1 = 0.0451$. Substituting the known values in this equation, and solving for h_0, we find $h_0 = 0.0048$. In group 7, Table 8, the value of η/h_0 for $\beta = 120°$ is 1.962, whence $\eta = 1.962 \times h_0 = 1.962 \times 0.0048 = 0.0094$. Clearance ratio $= \eta/a = 0.0094/5 = 0.00188$. Friction coefficient factor $\lambda a/h_0$ is found from group 12, Table 8, to be 2.902, to which the correction factor L_1/F_1 must be applied. Hence,

$$\lambda = \frac{h_0}{a} \times 2.902 \times \frac{1}{L_1/F_1} = \frac{0.0048}{5} \times 2.902 \times \frac{1}{0.710} = 0.00392$$

3. LOADING AND FRICTION OF PIVOTED SHOE BEARINGS

Pivoted shoes are applicable to straight-line motion as in cross heads, and to rotary motion as in both journal and thrust bearings. In rotary motion they may be fitted to any surface of revolution, whether flat (Fig. 43), cylindrical (Fig. 44), conical, or spherical (Figs. 45 and 46). The mean diameter d is purposely made common to all these figures, being the journal diameter for some and the mean thrust face diameter for the others.

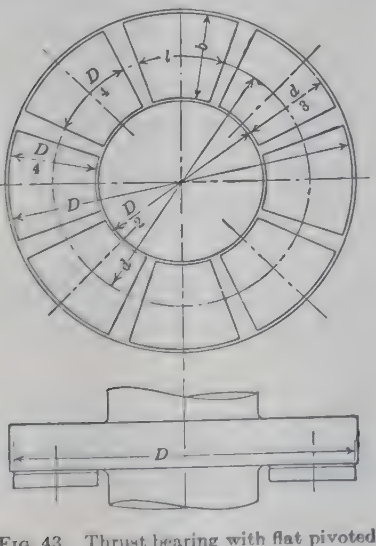

FIG. 43. Thrust bearing with flat pivoted shoes.

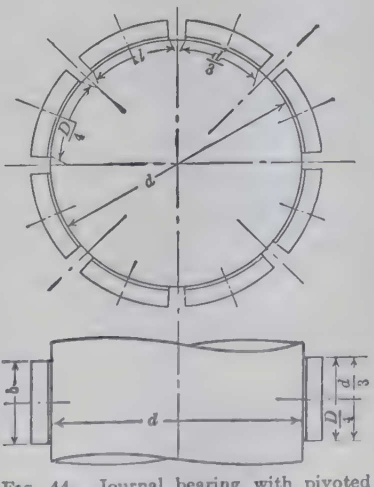

FIG. 44. Journal bearing with pivoted shoes fitted to cylindrical surface.

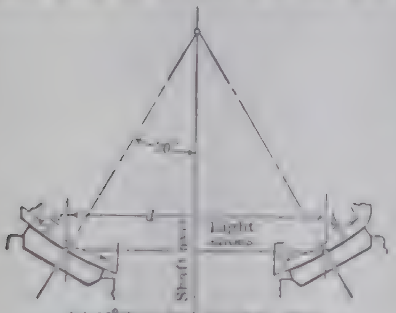
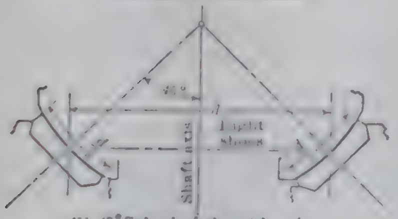
Although the shoe faces in the foregoing figures are shown to be "square" (with mean length equal to width), they can and do have other proportions than $l/b = 1$. This variation is seen in thrust bearings in Fig. 47, which illustrates the use of six and eight shoes, with the same inside, mean, and outside diameters. The usual standards of those diameters are two to one, the mean being three-fourths the outside diameter. The standard sum of the face angles is as shown, equal to 306°, the remaining 54° being equally distributed for oil channels.



(a) 30° Spherical thrust bearing with eight pivoted shoes



(b) 45° Spherical thrust bearing with eight pivoted shoes

FIG. 45. Spherical thrust bearings for suspended loads. Lateral capacity depends on the angularity and the applied thrust load.

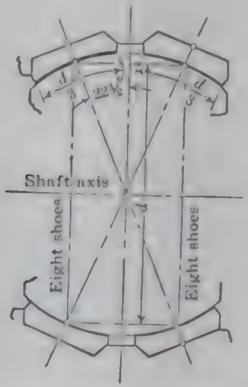


FIG. 46. Spherical journal bearing with two balanced sets of eight pivoted shoes. These bearings have an axial capacity proportional to angularity.

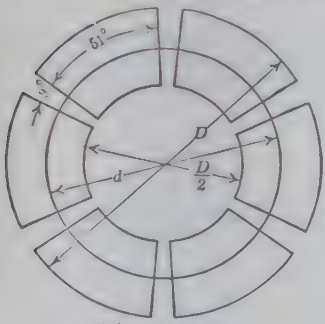
The mathematical analysis of the relative carrying capacities and friction of pivoted shoes, of varying length-width ratios, has been made for straight-line motion, such as that of a cross head, but with continuous uniform speed. See Fig. 48 for the midsection of a pivoted shoe and its film, supporting a collar. The position of the pivot must be right, both radially and circumferentially, in order to balance the pressures of a correctly shaped film.

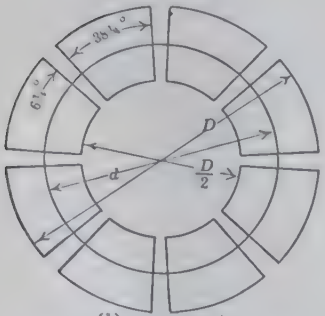
The fundamental relationship of the variables involved in the study of straight-line motion of pivoted shoes carrying a load upon flat-wedge films of lubricant, without metallic contact, is given in the following equation for conditions known as Case 2 optimum load. (See discussion of optima on pp. 12-09 ff.)

$$h_0^2 = \frac{1.92\mu v l L_1}{p_0} \qquad (49)$$

In this formula v is velocity, feet per second; μ is the viscosity, Reyns; l is the mean length of the shoe face, inches; and p_0 is the average film pressure, pounds per square inch.



(a) Six shoes



(b) Eight shoes

FIG. 47. Comparison of thrust bearings with six and eight shoes.

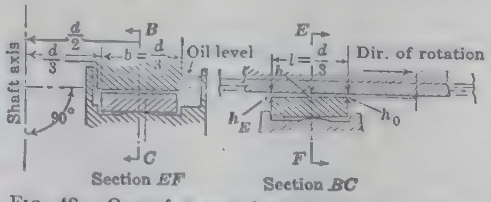


FIG. 48. One of a set of pivoted bearing shoes, showing pivot and constraints.

The factor L_1, called the side-leakage correction factor for pressure, has been found to vary with shoe face proportions according to laws determined by Kingsbury, Martin, Needs, and others. The Kingsbury values of Fig. 18 will be used in this discussion.

COMPARATIVE CAPACITIES FOR DIFFERENT SHOE FACE PROPORTIONS. Several relationships of the variables in eq. 49 have been compared for length-width ratios ranging from 0.5 to 2.0, in order to find the best ones for general applications.

The purpose of the comparison was: (1) to evolve a rational system of loading of pivoted shoes, (2) to determine the relative merits of the different proportions as to capacity and friction, and (3) to obtain the basis for the loading tables (see Tables 10 and 11).

The proportions $l/b = 4/3$ have been common to six-shoe Kingsbury thrust bearings for many years. In Table 9 other shoe faces are compared with this face in various ways, the most interesting of which is p_0. Because both experience and engineering practice call for thinner films for shoes of smaller area than for those of larger area, other conditions being the same, a study was made of loading practice common over many years. The result is indicated by eq. 50, which will apply to a uniform series of similar standard thrust bearing shoes whose $l/b = 4/3$.

$$h_0 = (0.675 \times 10^{-10} vl)^{3/8} \tag{50}$$

By comparing similar total areas of eight different shapes, as they would apply to thrust bearings with full complements of shoes, the relative capacities $nR/6$ in Table 9 indicate that the greatest capacity is had by twelve shoes having $l/b = 0.667$ and the least by four shoes having $l/b = 2.000$. The relationships found in Table 9 form the basis for the loading tables for pivoted shoes.

Table 9. Comparison of Pivoted Shoe Bearing Performance

l/b	0.500	0.667	0.800	1.000	1.143	1.333	1.600	2.000
A	0.375	0.500	0.600	0.750	0.857	1.000	1.200	1.500
p_0	1.171	1.208	1.198	1.152	1.115	1.000	0.903	0.772
R	0.438	0.604	0.719	0.865	0.955	1.000	1.083	1.158
n	16	12	10	8	7	6	5	4
$nR/6$	1.171	1.208	1.198	1.152	1.115	1.000	0.903	0.772

Notation: l/b = length/width ratio; A = relative area per shoe; p_0 = relative mean pressure on shoe; R = relative capacity per shoe; n = number of shoes in bearing.

Assumed conditions: Viscosity, speed, and widths constant. Film thicknesses vary according to eq. 50.

LOADING, FRICTION, AND FILM THICKNESS TABLES FOR PIVOTED SHOE BEARINGS. Tables for Thrust Bearings. Because of the wide use of six-shoe thrust bearings like those shown in Fig. 47*a*, Table 10 was prepared. In Table 11 similar data are given for eight-shoe bearings (Fig. 47*b*), which, for a given occupied space, have greater mechanical strength as well as greater film capacity. For simplicity the data are given for one shoe whose area in square inches is tabulated under A_s. The mean speeds v_d are those for the mean diameter d. The rpm tabulated opposite N_d is that which will produce the mean surface speed v_d feet per second for the mean diameter d inches. The average pressure, in pounds per square inch over the shoe face, is tabulated opposite p_0. Hence the load carried by one shoe will be the product of A_s and p_0, pounds. The horsepower friction loss per shoe will be as marked opposite H_s when the mean viscosity of the film is 3.4×10^{-6} Reyns (pound-seconds per square inch), equivalent to 0.2345 poise or to 23.45 centipoises. For SUS Saybolt universal seconds equivalents, see Table 1, Article 13, of this section.

For the six-shoe bearings (Table 10) the following equations may be used to calculate sizes not included in the table:

$$p_0 = \frac{0.2705 \mu v d}{h_0^2} \tag{51}$$

$$h_0 = (0.3 \times 10^{-10} vd)^{3/8} \tag{52}$$

$$H_s = 1.465 \times 10^{-2} \mu \frac{A_s v^2}{h_0} \tag{53}$$

For the eight-shoe bearings (Table 11) the equations are

$$p_0 = \frac{0.28 \mu v d}{h_0^2} \tag{54}$$

$$h_0 = (0.2616 \times 10^{-10} vd)^{3/8} \tag{55}$$

$$H_s = 1.494 \times 10^{-2} \mu \frac{A_s v^2}{h_0} \tag{56}$$

The equations for p_0 and H_s include the side leakage factors L_1 and F_1 found from Fig. 18.

(*Continued on p. 12-36*)

Table 10. Load Capacity and Friction Horsepower of 51° Thrust Shoes (Fig. 47a)

For six-shoe bearing, total thrust = $6A_sp_0$ and total friction hp = $6H_s$

Tabular values are based on $\mu = 3.4 \times 10^{-6}$ lb-sec per sq in. (Reyns), equivalent to 0.2345 poise or 23.45 centipoises. When loading shoe higher than tabular value of p_0, increase viscosity in same ratio to maintain film thickness. Horsepower loss will increase in same ratio.

Table 11. Load Capacity and Friction Horsepower of 38¼° Thrust Shoes (Fig. 47b)

For eight-shoe bearing, total thrust = $8A_sP_0$ and total friction hp = $8H_s$

Tabular values are based on $\mu = 3.4 \times 10^{-6}$ lb-sec per sq in. (Reyns), equivalent to 0.2345 poise or 23.45 centipoises. When loading shoe higher than tabular value of p_0, increase viscosity in same ratio to maintain film thickness. Horsepower loss will increase in same ratio.

It must be remembered that the pressures tabulated for the various conditions in Tables 10 and 11 are based on a uniform viscosity. When loading the shoe more heavily than the tabular p_0 the viscosity should be increased in the same proportion, in order to maintain the tabular minimum film thickness. This obviously increases the power loss H_s in the same direct proportion. Hence the designer can load a bearing up to any desired pressure within the mechanical strength of the bearing elements, if he is careful to lubricate it with oil of the required viscosity range and to cool that oil so that it will have the desired mean viscosity at the mean operating temperature of the film.

Tables for Journal Bearings. When the journal is surrounded by a set of equally spaced similar pivoted shoes, as suggested by Fig. 44 for eight square-faced shoes, the shoe loads, because of film pressure generated by rotation, are equal only when all the films have the same thickness, as they do when the journal surface is equidistant from all their faces. This can occur only when there is no externally applied radial load, because the result of such a load is to thin the films on the loaded side of the journal and to thicken those on the other. If the bearing is to carry practically no radial load, the radial running clearance, for Case 2 optimum operation (see p. 12-11), could be as low as 1.594 times the h_0 value given by Table 11 for a mean diameter d equal to the journal diameter. With no radial load the film viscosity is useful only as a damping means and could be anything within reason. The lower the viscosity, the less would be the power loss. However, it is the present problem to learn how such bearings react to definite radial loads and to find out what the running clearance should be when thus loaded.

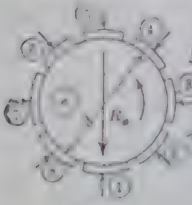

FIG. 49

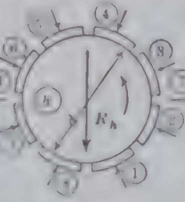

FIG. 50

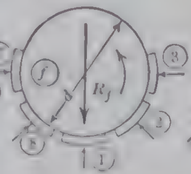

FIG. 51

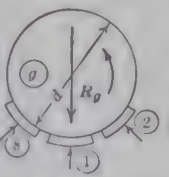

FIG. 52

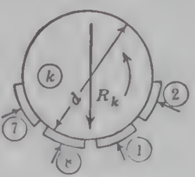

FIG. 53

In vertical shaft service the journal is normally surrounded by pivoted shoes as in Fig. 44. There are, therefore, three simple ways such a journal can present its load to the pivoted shoes. One way is seen in Fig. 49 with the load always acting toward one shoe. A second way is seen in Fig. 50, with the load always acting toward the space between two adjacent shoes. The third way is for the load direction to follow the rotation of the shaft.

In horizontal shaft service full sets of shoes are also used, but other arrangements are feasible and common as seen in Figs. 51, 52, and 53. The load direction is indicated in each figure.

As film thicknesses are minute compared with their journal diameters it is customary in studying them to represent the bearing by a circle whose radius is the radial clearance η and to indicate the journal as a point O' within that circle, with more or less eccentricity c. This method may be applied to pivoted journal shoes by representing the latter as a series of tangents to the clearance circle, as seen in Fig. 54.

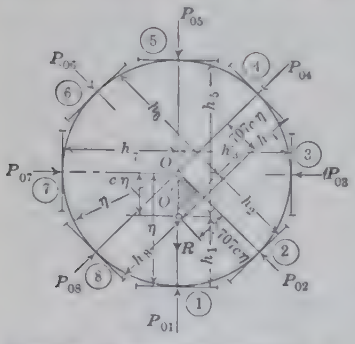

FIG. 54. Geometrical relations between clearance and eccentricity of a pivoted-shoe journal bearing.

The journal position is shown at O', a distance $c\eta$ below the clearance circle center O, Fig. 54; c is the eccentricity factor. The clearance circle has eight tangents representing eight pivoted shoes which are numbered 1 to 8 counterclockwise. The distance from the journal to each shoe, which is the mean film thickness, is shown by h with the shoe number as a subscript.

Radial Load Acting toward One Shoe. In Fig. 54 the mean film thicknesses h will be

$$h_1 = (1 - c)\eta \qquad h_2 = h_8 = (1 - c\cos 45°)\eta \qquad h_3 = h_7 = \eta$$

$$h_4 = h_6 = (1 + c\cos 45°)\eta \qquad h_5 = (1 + c)\eta$$

It is known from eq. 49 that

$$p_0h_0^2 = 1.92\mu vlL_1$$

As the shoes of this journal bearing have the same square proportions as those of the eight-shoe bearings of Fig. 47b, the data given in Table 11 can be used for reference. The general formula given above can be put into the more useful arrangement, $p_0h^2 = K$, by replacing h_0 by the mean thickness h, which equals $1.594h_0$ for Case 2 optimum load (see p. 12-11). The value of K will therefore be as given in the following equation for square-faced shoes ($l, b = 1$) whose mean diameter is $d = 3l$ and for which $L_1 = 0.437$:

$$p_0h^2 = K = 0.7105\mu vd \tag{57}$$

Analysis of a bearing like Figs. 49 and 54 shows that there is a best eccentricity, so far as carrying capacity is concerned, when the least film thickness has the value tabulated in the thrust bearing (Table 11).

The relations between eccentricity, radial clearance, and mean film thickness have already been given. It therefore remains to determine the average radial pressure p_0 for each of the eight-shoe faces. Because all faces have equal areas, it is not necessary to introduce them here.

When the radial pressures are known, their components parallel with the journal load may be found and lettered P'_0 with a subscript after the subscript zero to show the shoe number. Hence, for Fig. 54,

$$p'_{01} = p_{01} \qquad p'_{02} = p'_{08} = p_{02} \cos 45° \qquad p'_{03} = p'_{07} = 0$$

$$p'_{04} = p'_{06} = -p_{04} \cos 45° \qquad p'_{05} = -p_{05}$$

Radial Load Acting toward Space between Two Shoes. Similar analysis shows that if the radial load acts toward the space between two shoes, as in Fig. 50, the radial capacity is substantially the same as for Fig. 49, for the same radial clearance and the same eccentricity. Hence, if a shaft is out of balance, and if that is the cause of the radial load on the bearing, the film resistances to radial displacement will be substantially constant throughout the revolution of the shaft, whose axis will describe a circle with radius of $c\eta$.

The shoe arrangements in Figs. 44, 49, and 50 are usual in vertical shafts. Those of Figs. 51, 52, and 53 are suitable for horizontal shafts. The two side shoes three and seven of Fig. 51 do not add to the vertical capacity of the bearing but do add to the journal stability where there is some change of load direction, not exceeding 30° approximately. At the same time, however, they increase the friction loss.

Friction Losses in Pivoted Shoe Journal Bearings. The friction losses in journal bearings having eight square pivoted shoes may now be investigated. The loss per shoe is determinable from eq. 56 for H_s. It is seen to vary inversely as the minimum film thickness and directly as the viscosity. The mean thickness $h = 1.594h_0$ can be introduced giving the following equations, in which the viscosity is assumed to be $\mu = 3.4 \times 10^{-6}$ Reyns:

$$H_s = \frac{8.1 \times 10^{-8}A_sv^2}{h} \tag{58}$$

$$H_s = \frac{2.382 \times 10^{-2}\mu A_sv^2}{h} \tag{59}$$

Loading and Friction Tables for Journal Shoes. In order that a wide variety of problems involving pivoted shoe journal bearings like those shown in Figs. 49, 51, and 52 may be readily solved, Table 12 has been prepared. For sizes and conditions not included in the table, eqs. 57 and 59 may be employed. Comparing this table with Table 11 shows that the first three tabular values of each block are alike, as would be expected. The fourth entry in the blocks of eight values is the radial clearance for greatest radial capacity for eight square-faced shoes. As $c = 0.5$, the least mean film thickness, which is over shoe 1, will be $h_1 = (1 - c)\eta = 0.5\eta$ (see Fig. 54). Also, from the Case 2 optimum load requirement that $h_1 = 1.594h_{01}$, $\eta = 3.188h_{01}$. Because the film thicknesses, pressures, etc., vary from shoe to shoe in a loaded radial bearing, the subscript 1 is added to p_0 and h_0, making them p_{01} and h_{01} to show that the values tabulated refer only to the most heavily loaded shoe 1.

The next pair of tabular values, R_8 and H_8, refer to a bearing like that of Fig. 49. They are the total load, and the friction for all eight shoes, when the minimum film thickness of the nearest shoe 1 has the value tabulated opposite h_{01} and when the average pressure over the face of that nearest shoe 1 has the value tabulated opposite p_{01}.

The last pair of tabular values R_5 and H_5, in the blocks of eight in Table 12, refer to a bearing like Fig. 51. They are totals for all five shoes. The values tabulated for P_0 and h_{01} refer to shoe 1 of the group of five. When the side shoes 3 and 7 are omitted, as in Fig. 52, the total load carried by the remaining three is equal to R_5. The total friction for the three will be equal to $0.717H_5$.

Load capacity and friction for bearings like those shown in Figs. 50 and 53 have not been tabulated but may be calculated by following the procedure described. Performance of a bearing like that of Fig. 50 is approximately the same as performance of one like that of Fig. 49.

The Loading and Friction of 38¼° Journal Shoes Wider and Narrower than Square. Table 12 for square journal bearing shoes, i.e., the ones for which $l/b = 1$, can be used to obtain the capacity and other data for *wider* and *narrower* shoes of the same angular

Table 12. Load Capacity and Friction Horsepower of 38¼-degree Pivoted Shoe Journal Bearings

R_8 and H_8 denote total radial load capacity and total friction horsepower, respectively, for an eight-shoe bearing (Fig. 49). R_5 and H_5 denote corresponding values for five-shoe bearing (Fig. 51).

Table is based on $\mu = 3.4 \times 10^{-6}$ lb-sec per sq in. (Reyns) equivalent to 0.2345 poise or 23.45 centipoise. When loading higher than the tabular value of p_{01} or H is required, increase the viscosity in the ratio of pressure in order to maintain film thickness. Horsepower loss will increase in the same ratio.

length of 38 1/4°. This will be explained below, taking account of the differences in the influence of side leakage upon capacity and friction, and also of the requirements of the film thickness philosophy already explained.

The problem is illustrated in Figs. 55 and 56 with a journal having diameter of $d = 3.00$, surrounded by eight shoes of length $l = 1.0$. They are assumed to be pivoted members, suitably mounted. In Fig. 56 several different vertical sections of shoes for such a bearing are shown, the shaded portions indicating a width $b = 1.00$, which also equals the shoe face length l of Fig. 55. However, Fig. 55 might represent shoes of any width b. Eight different values of b are indicated in Fig. 56, ranging from 3.0 down to 0.75. They will now be compared.

The philosophy of loading underlying pivoted thrust shoe practice, explained heretofore and applied to the derivation of the thrust shoe loading tables and to the choice of a best shoe form, becomes of new interest now. Equation 50 is re-expressed below as applied to the comparison, in minimum film thickness, of two shoes of uniform proportions, operating at the same surface speed. The areas have been introduced because they will vary as the square of the similar linear dimensions:

$$\frac{h_0}{h_{01}} = \left(\frac{l}{l_1}\right)^{3/8} = \left(\frac{A_s}{A_{s1}}\right)^{3/16} \tag{60}$$

By the above equation we can find the relative minimum thickness for square shoe faces. Our loading philosophy proposes the same thickness of film for two shoes of the same area but with different face proportions.

With the relative minimum thicknesses for the films for the eight shoe faces the capacities of those shoes can be found by first getting the average pressure p_0 from eq. 49, p. 12-32. It applies to Case 2 optimum films.

After p_0 is found, the capacity of the face can be determined by multiplying p_0 by A_s. Thus by means of eqs. 60 and 61 we can determine the relative capacities and suitable film thicknesses for the lower (most heavily loaded) shoes of eight shoe bearings (Fig. 55) whose shoe face widths are narrower or wider than square, as indicated in Fig. 56. The comparisons are made for common operating conditions as to viscosity and surface speed.

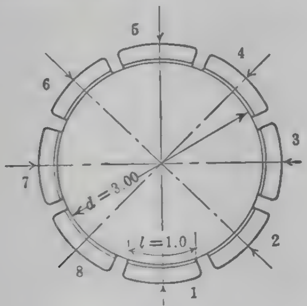

FIG. 55. Eight-shoe journal bearing having shoes of constant length l.

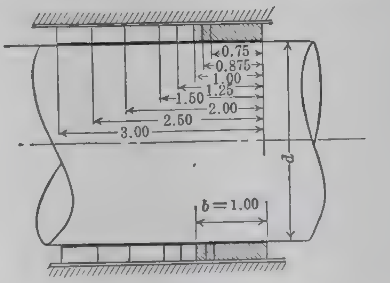

FIG. 56. Shoes of varying width b, for bearing in Fig. 55.

$$\frac{p_0}{p_{01}} = \left(\frac{h_{01}}{h_0}\right)^2 \frac{(L_1)}{(L_1)_1} \tag{61}$$

The general friction equation giving horsepower loss per shoe, with side leakage correction factor F_1, is as follows for Case 2 optimum:

$$H_s = 1.645 \times 10^{-2} \mu F_1 \left(\frac{A_s v^2}{h_0}\right) \tag{62}$$

This may be applied to obtain the power loss of the most heavily loaded shoe of the set whose least film thickness was found by eq. 60 as described just above.

Equation 62 can be used as follows for comparison of different shoes, just as was eq. 60, for constant μ and v:

$$\frac{H_s}{H_{s1}} = \frac{(F_1)}{(F_1)_1} \frac{A_s}{A_{s1}} \frac{h_{01}}{h_0} \tag{63}$$

In Table 13 the different shoe faces are compared with a square face.

Table 13. Comparison of Capacities and Friction for Journal Shoes Not Square

l/b	0.333	0.400	0.500	0.667	0.800	1.000	1.143	1.333
A	3.000	2.500	2.000	1.500	1.250	1.000	0.875	0.750
h_0	1.229	1.187	1.139	1.079	1.043	1.000	0.975	0.948
p_0	1.183	1.200	1.207	1.162	1.097	1.000	0.937	0.806
Ap_0	3.549	3.000	2.414	1.743	1.371	1.000	0.820	0.604
H	2.595	2.226	1.836	1.429	1.216	1.000	0.889	0.774

Notation. l/b = length/width ratio; A = relative area per shoe; h_0 = relative minimum film thickness; p_0 = relative mean pressure on shoe; H = relative horsepower.

Assumed conditions. Minimum film thicknesses from eq. 60. Mean pressure from eq. 61. Horsepower from eq. 63.

Now, if the minimum film thickness of one square shoe, of any area, is known its area may be treated as unity, and the corresponding thicknesses for larger and smaller square shoes found. The new thicknesses may then be applied to the wider or narrower shoes.

EXAMPLE. An eight-shoe journal bearing like the one shown in Fig. 55, when d = 18 in., is required to have shoe faces that are 12 in. wide, i.e., twice as wide as the 6-inch square shoe for which data are given in Table 12. The speed is to be 10 ft per sec and $\mu = 3.4 \times 10^{-6}$ Reyns. For this problem the relative area = 2 and relative minimum film thickness = 1.139 (Table 13), and they will apply to the lower or most heavily loaded shoe of the set of eight.

This means that the proper minimum film thickness for the 6- by 12-inch shoe will be 1.139 times that tabulated in Table 12 for the 6-inch square shoe or 1.139 × 0.000754 = 0.000858. The relative average pressures on the two shoes will then be as seen in Table 13, i.e., 1.207 × 303 = 365.7 psi. Hence the radial load upon the lower 12-inch wide shoe would be 72 × 365.7 = 26,330 lb.

It is apparent that the total radial capacity of the eight 12-inch wide shoes of Fig. 55 for d = 18 in. will be determined by the running clearance. The eccentricity factor should still be c = 0.5. The radial clearance r = 0.002404, given in Table 12, must therefore be increased to 0.002738, i.e., in the same proportion 1.139 as was the minimum film thickness h_0 over the lower shoe, which was raised from 0.000754 to 0.000858.

The net capacity R_s of the eight 6- by 6-in. shoes in Table 12 will have to be increased, first by the pressure factor 1.207 and second by the area factor 2.0 in order to obtain the actual capacity, 2.414 × 16,850 = 40,676 lb.

To obtain the power loss, the tabular loss H_s must be increased by the factor 1.836 due to the combination of greater area of shoe faces, better face proportions, and greater film thickness. Therefore actual power loss = 1.836 × 1.12 = 2.06.

The foregoing values cover a full complement of eight shoes. When the upper three are removed the net capacity of the bearing will be increased from 40,676 to 2.414 × 20,200 = 48,763 lb, but the friction loss will be reduced from 2.06 to 1.58 hp. (See Table 12.)

This a typical block of factors has been found with the resulting tabular values that would apply to a journal bearing supported by $38\frac{1}{4}°$ pivoted shoes whose axial width is twice as great as the width of the square-faced shoes covered by Table 12.

The capacities thus far tabulated for pivoted shoes are based on the use of a light oil. If the film viscosity should be increased tenfold, the film capacity would be increased tenfold. Whether or not a pivoted bearing is mechanically strong enough to sustain such a heavy load is a matter of design.

4. CONSTRUCTION AND STANDARDIZATION OF JOURNAL BEARINGS

JOURNAL BEARING ELEMENTS. Classification. Figures 57 to 75 serve to illustrate and classify the usual ways that journal bearings are applied to heavy machinery. For ordinary service where axial loads are light the plain cylindrical journal bearing serves well.

Running friction is less than for so-called antifriction bearings for moderate speeds, and *durability* greater for high speeds.

Starting Friction. When the loads in a machine are created by its operation the starting friction is negligible. When the loads are heavy before starting, the starting friction is high and it is sometimes necessary to make provision for lessening it. Several effective ways are available, and manufacturers should be consulted about them. One means frequently resorted to is high-pressure oil that forces into the bearing a preliminary film upon which the starting is very easy indeed, easier than for any other type of bearing. See Fig. 5 and text for the laws of fluid flow involved.

Standardization of plain journal bearings has not taken place effectively because they are so simple and easy to make. Hence suppliers of bushings carry enormous stock lists of sizes. There is a strong tendency toward babbitt-lined shells of steel or bronze of light accurate construction which are entirely practicable when the housing in which they are mounted is stiff. Many solid bronze bearing shells are now also made of pressed powdered metals.

Standardization of mountings is even more difficult than for the bearing shells. The direction which this might take is indicated in Figs. 72 to 75, in which the barrel and shell portion would be common to all. See methods of lubrication, Article 5.

Operating Characteristics. The relation of running clearance to speed, viscosity, and load has been discussed at length heretofore. In Article 9, Optimum Loading and Current Practice, this question is answered: How thin should the film be allowed to become during operation? Therein the wide variation of clearance met with in practice is also shown. With this information available there should be a gradual approach toward greater uniformity of design.

OIL GROOVES IN JOURNAL BEARINGS. Oil should be applied to a journal bearing at the point where there is no load, or where the load is lightest if it changes its radial direction. Grooves, therefore, may be used for the following purposes: (1) the application of oil, (2) the collection of side leakage, and (3) the pumping of oil.

Application grooves should be parallel with the shaft. The length may vary from an oil hole diameter to the full length of the bearing surface. Such grooves usually do not extend to the sides. (See Fig. 76.) While two such grooves frequently are cut diametrically opposite, one usually is enough. The grooves should be rounded on the edges parallel to the shaft. If the bearing revolves about a fixed shaft, the groove should be in the shaft on the unloaded side.

If a load exerted by a shaft turning in a fixed bearing acts successively in all radial directions with a known portion of the shaft journal subjected to little or no load, the oil grooves should be located in the shaft at that place if practicable. Oil may be supplied to the groove through the shaft or from a ring groove at one side of the bearing, registering with one end of the groove in the shaft. Figure 77 shows grooving for use where the direction of the radial load is unknown. This arrangement presents a fair bearing surface to the journal whenever the region of closest approach of the bearing surfaces passes over an oil groove. With pressure oiling, the circumferential groove may be omitted, thereby increasing the carrying capacity of the bearing.

High-speed journals are cooled by continuously changing the oil. It then is necessary to provide oil outlets at the ends of the application grooves, as in Fig. 78. The grooves must be large enough to pass the desired quantity of oil with the pressure available. In Fig. 77 outlets would be provided at the ends of the laterals. The cross section of the application groove may be, in general, similar to that shown in Fig. 76. If the grooves are used to limit the areas of the bearing surface, they sometimes are enlarged as shown in Fig. 79.

Collector grooves are circumferential grooves at the sides of automatically or pressure-oiled bearings. They collect side leakage and return it to the oil well to prevent its being wasted by flow along the shaft. Such grooves usually are single, but frequently double. They should have an adequate discharge hole at the bottom. They should be continuously circumferential without a break. Oil application grooves should not enter the collector grooves. (See Fig. 80.)

Pumping grooves are used both to pump and to apply oil. The most common type is the helical groove used with a vertical shaft to lift oil from the well to the upper end of a bearing that may be higher than the surface of oil in the well. The most effective pumping groove is circumferential, if it stops short of extending all the way around the shaft, and is cut in the stationary bearing surface. The inlet end must open to the oil in the well in a manner that will readily receive oil. The other end must be dammed in the circumferential direction. From this point, suitable passages lead oil to any location within the limits of the available pressure. It simply may be led along the shaft through application grooves. Pumping grooves should be completely submerged in oil to avoid aeration of the oil bath. Aeration is, at best, hard to control in high-speed bearings.

The cross section of a pumping groove should be shallow radially. The shallower the depth the greater will be the pressure developed, but the less the discharge. The wider the axial width the greater will be the rate of discharge. For calculations involved in design, see Viscous Flow, p. 12-03. Ordinarily a simple groove of cross section shown in Fig. 76, but shallower, will be satisfactory.

Many self-contained systems have been devised to lubricate the journal and thrust bearings of a machine continuously, which cause oil to flow to all surfaces needing it, and then return it to the well. Bearings so lubricated are durable and require a minimum of care. (See Figs. 81 and 89.)

5. LUBRICATION AND COOLING OF BEARINGS

LUBRICATION. Bearings are lubricated by these systems: (1) automatic, (2) intermittent, (3) bath, (4) splash, (5) pressure, and (6) mechanical.

Automatic Lubrication. The rotation of the shaft causes oil to be fed to the bearing surfaces. Lubrication ceases when the shaft stops turning. The systems in common use are ring oiling, chain oiling, disk oiling, capillary oiling, waste pack oiling, vacuum oiling, and oiling by means of a shaft-driven pump of any type. All these systems lift oil to the bearing from a well below it and are capable of continuous operation for long periods, because oil leaking from the ends of the bearing or elsewhere returns to the well and is used over again. (See Fig. 81.)

Intermittent Lubrication. Oil is applied to the bearing at intervals from a source independent of the rotation of the shaft. The simplest, but least dependable system, is hand oiling from an oil can. Cup oiling is better, as it has the possibility of being practically continuous and uniform, with visible and adjustable rate. Wick oiling, with textile or metal wicks, is, next to hand oiling, the simplest and cheapest system. The number of wick strands determines the rate of supply. The wicks filter the oil. The general faults of intermittent systems include usually complete loss of oil after it leaves the bearing, frequent refilling of cups and wells, and inadequate or wasteful oiling by reason of ignorance or carelessness.

Bath Lubrication. The bearing faces are completely immersed in oil at all times. This system is used for vertical shafts, and is simplest for the lower end, where thrust and radial bearings can be combined. At other places on the shaft, the well may be formed by a revolving bowl, or the well may be like the one shown in Fig. 82. This last system is commonly used for thrust bearings placed anywhere along a vertical shaft. Packing may be used in stuffing boxes to hold oil in any kind of a recess about a bearing, horizontal or vertical, that will make it a bath-oiled bearing. Oil will leak away, even though slowly, from such a bearing. There also is the danger of setting up the packing so tightly that it will run hot and the shaft will be worn within it.

Splash lubrication was common in the crank cases of internal-combustion engines and still is considered a simple way to oil all the bearings of a trunk-piston engine. The splash is produced by the lower ends of the connecting rods dipping into the oil in the crank case. There are various refinements to control the splash. This might be considered a continuous system, because most of the oil is returned to the crank case to be used again, although partly contaminated or broken down by exposure to cylinder walls. The system is used in compressors and other crank machines.

Pressure Lubrication. Pipes lead oil to the bearings from a source of oil under pressure. The pressure is available at the point of application of oil to the bearing and will therefore tend to keep oil passages open. Bearings with this system usually are simple when the whole machine is so enclosed that oil will drain to the sump from which an oil pump redistributes it to the bearings. The rate of oil supply to each bearing may be regulated by making the size of the supply hole to suit the pressure in the system. The source of oil may be independent of the operation of the machine, as when a separate motor-driven oil pump is used. It may otherwise be driven by some shaft in the machine, and, therefore, operates only when the machine is running. Each method has its drawbacks, and judgment must be used in selection.

Mechanical Oilers. A variety of mechanical devices are on the market for producing what may be styled centrally controlled, intermittent lubrication of bearings. They eliminate oil cups, but introduce a multitude of small oil pipes, through which oil is fed or forced intermittently, in measured amounts. These devices usually operate by ratchets driven from the shaft of the machine whose bearings they oil.

Lubrication of Vertical Journal Bearings. With pressure lubrication, the simplest bearing form may be used. The journal surface may be on the shaft itself. To collect the oil flowing down the shaft below the bearing, a collar on the shaft throws the oil into a stationary pan, whence it flows to the sump of the oiling system. (See Fig. 83.)

Vertical journals may be on the surface of sleeves shrunk or otherwise fastened on the shaft. (See Fig. 82.) The lower end of the sleeve, which is bored out larger than the shaft, projects into the stationary oil pan. Oil may be taken into the bearing film by capillarity, by viscosity pumping, centrifugally, or by combinations of these methods.

If the shaft terminates at the bottom in a vertical journal bearing, lubrication is a relatively simple problem. With a through shaft, simple constructions also may be used, if lubrication is by cup, and if some waste of oil or grease is unimportant. Leakage along the shaft may be minimized by a stuffing box if the speed of rotation is not so high as to cause heating of the shaft by the packing.

COOLING OF BEARING OIL. To keep oil in a bearing at a safe temperature, the heat of friction due to operation must be dissipated. Safe temperature depends on the kind of oil used and the conditions against which the bearing must be protected. Thickness of oil film and heat of friction both increase with viscosity of oil.

Direct Air Cooling. The oil housing surrounding the bearing should be sealed tight to prevent leakage. The oil then is allowed to warm up sufficiently to dissipate friction heat to the surrounding air by radiation and convection. As the oil heats it becomes less viscous and the friction loss in the bearing decreases. The rate of radiation and convection increases as the oil gets warmer. When heat generation and heat dissipation become equal the oil temperature will remain quite uniform, being affected only by changes in the surrounding air temperature. In air-cooled bearings the oil level should be watched and new oil added, as required, to replace that lost by leakage and evaporation.

Direct water cooling is applied in three ways, (1) water-cooling coils in the oil within the housing, (2) water-cooled shells or shoes, (3) water-cooled shafts or collars. With all these applications water must be circulated fast enough to remove the heat of friction from the oil and keep it at a safe temperature. When water-cooling coils are used in the housing, the oil should have a pour test point considerably lower than the temperature of the coldest cooling water, to prevent congealing on the coils.

Self-contained Unit Circulating System. Each machine in which bearings are installed has an individual oiling system that circulates oil through all bearings. Within the system are means for air-cooling or water-cooling the oil, depending on the amount of friction heat to be dissipated. Siphoning of oil back through the inlet pipe should be prevented by placing its opening above the oil level or by providing an air vent hole.

Central Station System. With this system oil should be circulated through the housing of each bearing at the rate recommended for each case, to lubricate the bearing and carry away the friction heat developed. The piping in such a system often is so extensive that the oil will be sufficiently air cooled in making the circuit. When necessary, however, the system is provided with water-cooling coils in the central station.

6. BEARING MATERIALS

METALS (see also Section 4, p. 4-73). Hardened steel will work well on hardened steel at low speed under very heavy loads. It is fairly durable even if imperfectly lubricated. The same metals work well at high speeds when carrying moderate loads if well designed, finished, and lubricated. Hard-surface bearings are least subject to abrasion by operation under adverse conditions. They are much used for small parts, but are too costly for large ones.

Gray cast iron is useful for bearing faces, especially if chill-cast. For moderate loads, such iron is excellent for both bearing surfaces, even for high-speed bearings, if properly lubricated. Cast iron works well with softer bearing materials, as babbitt metals and bronzes when properly lubricated, and can be made to carry high pressures.

Soft steel will run well with babbitt metals and other white metal bearings, and will carry considerable pressure if properly lubricated. It also will run directly on cast iron. Soft steel on soft steel is not recommended, because of the tendency to seizure. Hard steel on soft steel sometimes is useful. A carbon content of 0.30 to 0.40 is recommended for shafts running on soft metal bearings. Soft copper-base alloys containing lead are useful for moderate speed and heavy pressure. There is a tendency, however, to line brass and bronze bearings with a thin coating of white bearing metal. This avoids the tendency of high-copper alloys, when overheated in bearings, to destroy the finish of the opposing cast-iron or steel surface by roughening, plating it, or producing surface cracks.

Bearing metal alloys are discussed fully on pp. 4-73 to 4-78.

NONMETALS. Fiber (pressed paper) washers often are used for thrust bearings for low speed and considerable load, or high speed with light load when oil lubricated. **Jewels** of ruby or other crystals are used with hardened polished steel pivots in timepieces and instruments, oil lubricated. **Ivory** bushings are found in the best old clocks, with hardened steel pivots. **Hardwood** bearings have been used, lubricated by tallow and soaps.

Lignum Vitae. In the best applications lignum vitae is used with grain perpendicular to the bearing face. It is used to line stern tubes of ships, with fresh or salt water lubricant. The bearing in a vertical-shaft hydraulic turbine often has a lining of lignum vitae blocks in longitudinal grooves in the bearing shell. Adjustment is required to compensate wear. In this service they are lubricated with fresh water.

Rubber is used to line bearings where only water is available as lubricant and where bearing pressure is light. It is useful in guide bearing bushings for vertical revolving shafts, and in stern tube bearings in ships.

Resin-bonded Bearings. L. M. Tichvinsky gives the following résumé of literature on this bearing material:

> The rapid development of the phenolytic or resin-bonded bearings was directly connected with the steel mill industry. According to their structure and manufacture, the synthetic resin-bonded bearings can be classified into three groups: (1) manufactured from plain or graphitic molding powders, (2) manufactured from various felts of impregnated nonoriented fibers, (3) manufactured from laminated products.
>
> The bearings of group 1 are manufactured in great quantities for low load application, and for guide bearings of high-speed machines. High brittleness limits their application.
>
> Because of different bases, bearings of group 2 are tougher and more rigid than bearings of group 1. Their application is also for low or medium loads. Group 3 covers the most important type of bearings bonded with synthetic resin. They also are called laminated bearings because of their base consisting of woven textile fabrics. Occasionally, for less important performances, they are made from laminated paper products. In manufacturing these bearings high pressures and high temperatures are applied for a predetermined period of time during which the powdered synthetic resin liquefies. On cooling, a well-bonded product is obtained. These bearings are marketed under various trade names.
>
> For more severe operations, as in steel mills, these bearings perform most efficiently with water alone for both lubricating and cooling. The average physical and mechanical properties of a good laminated bearing material are: specific gravity, 1.25 to 1.40; weight (approx.), 0.05 lb per cu in.; Brinell hardness, 30 to 42; tensile strength, pounds per square inch (along grain), 8000–15,000; (across grain), 6000–11,000; modulus of elasticity, 1,000,000; compressive strength, pounds per square inch (perpendicular to laminae) 40,000–45,000; (parallel to laminae) 20,000–24,000; water absorption, 7-day test, 1–3%; oil absorption, negligible.

OIL-LESS BEARINGS. Although bearings are offered that are lubricated by other media than oil or grease, it is assumed here that the term oil-less bearing applies only to bearings to which no lubricant is expected to be applied. These comprise a wide variety of bearing shell materials with which lubricating substances are combined by one means or another in the process of manufacture. Among them are: (1) fiber, plain or impregnated with lubricant; (2) wood, plain or impregnated with lubricant, or with cavities filled with hard lubricant; (3) special highly graphitic alloys; (4) metal bushings with insets of hard lubricant; (5) press-molded mechanical mixtures of bearing materials and lubricants. Some of these materials will carry light loads at moderate speeds without serious wear. They are best suited to intermittent service or for very low speeds. Manufacturers should be consulted for detailed information concerning them.

7. MISCELLANEOUS JOURNAL BEARINGS

"INTERCHANGEABLE WITH BALL AND ROLLER BEARINGS." Study of the oil film type of journal bearing has indicated the possibility of their successful application within dimensions identical with those now used for ball and roller bearings. In the Nomy bearing, separate pivoted shoes are mounted in a ring that revolves with the shaft. The shoes bear on the inside of a stationary outer race. Provision is made for automatic lubrication. The Fast bearing has shoes integrally formed on the inner ring and connected thereto by stems. The bearing is quite rugged.

In neither of these bearings is the revolving element integral with the shaft. It, therefore, must be carefully fitted and clamped against the shaft, usually against a shoulder, and keyed or otherwise held to prevent slippage at starting. Otherwise these bearings are mounted in the same way as ball or roller bearings. A comparison of a bearing of this type and the more usual construction in which a bearing shell about one diameter long supports the shaft journal directly shows the space occupied to be about the same in both cases for similar service. Manufacturers should be consulted for detailed information.

ROLL-NECK BEARINGS. Roll necks in mills have long presented a serious problem, especially in steel mills. Early practice, still widely followed, was crude and very wasteful of power. The bearings were undependable. Wear on necks and bearings was considerable. The bearing equipment acted as a bar to the construction of larger mills. To remove this handicap, antifriction bearings have been used with considerable success, but have exhibited certain limitations.

Since 1930, the oil film type of bearing has been successfully applied to roll necks. One of these, the Morgoil bearing (Ref. 19), comprises a ground and polished steel sleeve or journal fitted over the roll neck, the latter being tapered at an angle of about 12°. The journal thus can be removed easily from the neck, which also can be made of larger diameter than is ordinarily possible. The sleeve is keyed to the neck. The bearing comprises a casing, into which is inserted a steel or bronze liner, faced with centrifugally cast babbitt. Oil for lubrication is pumped into the bearing through holes in the casing, and flows through appropriate grooves to a drain pipe. Tests described in the reference show this bearing to be capable of withstanding loads in excess of the roll-neck strength, and to effect considerable savings in power.

In Kingsbury roll-neck bearings installed on a wide strip mill of the Inland Steel Company, load was carried directly on the neck of the roll. The bearing shell was water cooled. Oil was fed to the bearing by a gravity system to make up leakage at the seals. High-pressure oil was introduced to reduce starting friction, permitting operation at any speed, irrespective of the load on the bearings. The friction was about the same as for roller bearings for all conditions.

8. MAKING AND FINISHING OF METAL BEARING SURFACES

SOFT METAL LININGS. Anchoring. For holding a soft metal lining to harder bearing surfaces the ordinary dovetail circular anchor is much used, but the T-head anchor is better because shrinkage of its neck holds the metal faces together. Anchors should be small and sparingly used, because they remove the backing of the soft bearing face by shrinking away from it. Sometimes they are omitted entirely. Small T-slot grooves are useful, especially if machined. Simple anchors sometimes are formed by a drill point or by plain grooves.

Tinning. In order that heat may pass freely from the bearing lining to its backing, the latter often is tinned. The surface to be tinned should be machined or ground smooth and must be clean. The shell should be heated, flux applied, and the tinning metal then spread thoroughly by scrubbing. It is best to tin the surface with the lining material. Usually with the residual preheat the shell is then ready to receive its soft metal lining. Some metals tin more easily than others. Steel and ordinary bronze are more easily tinned than cast iron and the aluminum- and other special bronzes. Copper plating before tinning improves the bond.

Peening. The value of peening or burnishing in the preparation of soft metal bearing faces is an open question. The resulting texture may be less uniform, even though sometimes harder. Peening holds the lining tightly to dovetail anchors, but peening a face that has been applied to a tinned surface is apt to loosen the tinned bond. Some alloys are hardened more by peening or burnishing than are others.

FITTING UNDER LOAD is useful for large vertical thrust bearings and often is used to compensate deflections produced by loads. In this process, a few turns at very low speed are made to spot the softer surfaces by the harder. A fairly heavy coating of lubricant will prevent overheating during the process. The hard face then is lifted and the rubbed spots on the soft face scraped down lightly. High spots on the harder face may be reduced by fine stoning. Usually all fitting is done on the softer face. The process is repeated until a fit of the desired extent and accuracy is obtained. The oil used with this fitting should be only heavy enough to get the desired marking on the bearing surface without injury or waste of time.

RUNNING-IN of bearings often is used as a system of inspection or of preliminary service. It sometimes is rather brutal, the journal being used to ream or burnish the bearing. It should not be taken as a substitute for good design and workmanship. See Fitting under Load, above. Running-in, if carefully done, will improve the bearing surface smoothness. It may be used in lieu of fitting under load with small machines. It is best, however, to premachine the bearing elements as nearly correct as possible, and to use designs and clearances suitable for immediate service.

FORMING. The hardest surfaces can be finished by grinding, and softer materials by machining, grinding, or scraping. The smoother and truer the surface the better will the bearing operate with proper lubrication. Lapping, after grinding, or over a smooth tool finish, is one of the best ways to produce accurately cylindrical, flat, or spherical surfaces on steel and cast iron. (See Section 23, Article 30.) Final finishing may be by rotation under a lightly pressing block of wood faced with leather, using fine abrasive and oil. Scraping, stoning, and filing are all useful for finishing and for fitting one surface to another. Smooth file finishing on a revolving shaft is common, but it will not true a surface initially out of round. Careful final finishing or fitting of the bearing surface is essential. A very smooth and accurate tool or grinder finish may not need further treatment. In important work, fitting of the softer bearing surface to the other or to a master surface by hand scraping is common. Thus, a bearing may be fitted to a mandrel of a diameter equal to that of the journal plus the desired running clearance.

EFFECT OF FINISH ON STARTING FRICTION. See Section 7, Article 13.

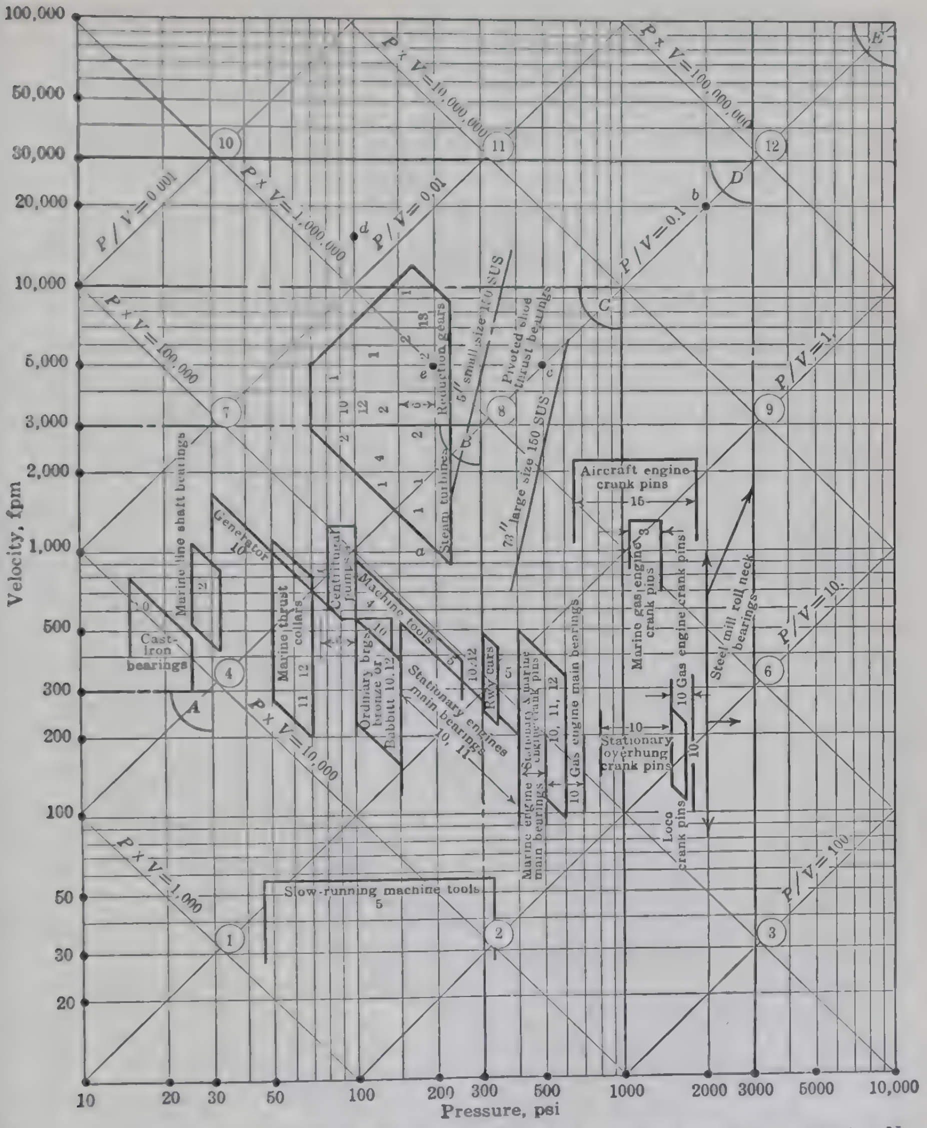

Fig. 84. Pressure-velocity experience chart. (Reproduced by permission from *Machine Design*, Nov. 1946)

9. OPTIMUM LOADING AND CURRENT PRACTICE

The current practice charted in Fig. 84 as to pressure and velocity is supplemented by running clearance data of Figs. 85 and 86. As little is said about the viscosity of the lubricant at operating temperature the designer is naturally in a quandary. Since it is the purpose of this review to help the designer, a table of least film thicknesses is proposed for properly designed journal bearings (Table 14).

It is assumed that the bearing film will extend over an angle of 120° and be of the Class C type (see p. 12-16) with running clearance. If operation is to be that for greatest capacity the characteristics will be those of Table 7 and Fig. 39 (p. 12-28) for $\beta = 120°$. If these relationships are maintained they will probably not agree with each of Figs. 84, 85, and 86.

Maximum load operation requires an eccentricity of $c = 0.469$. The following formulas are based on this condition:

$$\frac{Pa}{V\mu}\left(\frac{\eta}{a}\right)^2 = 0.228L_1 \tag{64}$$

$$\frac{H}{PV}\frac{a}{\eta}\frac{10^5}{a} = 9.36\frac{F_1}{L_1} \tag{65}$$

$$\frac{\lambda}{\frac{\eta}{a}} = 1.542\frac{F_1}{L_1} \tag{66}$$

$$\frac{\lambda}{\sqrt{\frac{\mu N}{P}}} = 0.533\frac{F_1}{\sqrt{L_1}} \tag{67}$$

For meanings of symbols see Article 2, p. 12-14, except that P is used instead of p_0.

When Table 15 is used for length-width ratios other than 1.00 the least film thickness should be chosen not according to journal diameter but from the projected area column of Table 14. Hence when $l/b = 0.5$, the axial width of the bearing will be about twice the journal diameter and its projected area twice that in Table 14 for that diameter. For example, if the journal diameter were 9 in. its width would be 18 in. with projected area of 162 sq in. The least film thickness for 1200 fpm would therefore be interpolated between 0.00168 and 0.001773, which would yield $h_0 = 0.00173$. Dividing this by 0.531 would give the radial clearance of $\eta = 0.00326$ in. Following this through, the operating viscosity of the lubricant would depend upon the load to be carried.

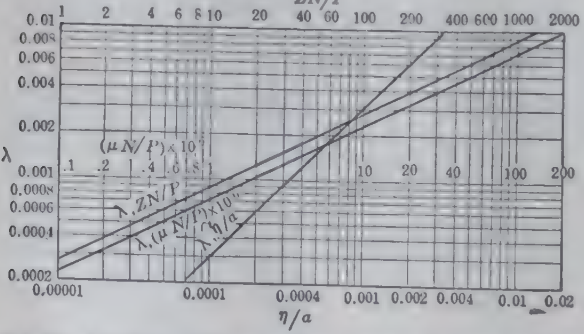

Fig. 87. Clearance, friction, and load-capacity factors for 120° centrally loaded clearance bearing with a width-diameter ratio of $b/d = 1$. (Reproduced by permission from *Machine Design*, Oct. 1946)

The current practice chart for loading (Fig. 84) is divided into zones representing degrees of conservatism, A to E, the letters appearing in a quadrant at the upper right corner of the zone. Zone A is obviously ultraconservative whereas zone D has few data points in it in the high-speed area but has many in the high-pressure area. Zone E may be said to be beyond the pale at present, judging by the dearth of plotted data.

For operating conditions other than optimum, reference must be made to the charts of general conditions. For centrally loaded clearance bearings, see Article 2, p. 12-14.

For a more comprehensive description of the tables and figures of this chapter, see Ref. 20.

BEARING CLEARANCES. A study of bearing clearances indicates wide divergences in practice. Figure 85 gives clearance data for marine bearings, horizontal bearings, vertical bearings, step bearings, Brown & Sharpe practice for over and under 600 rpm, respectively, the American Standards Association standards and British standards, up to a total clearance of 0.010 in. and diameters up to 8 in. Figure 86 extends this range to larger clearances and diameters. The line marked 0.001 diam. + 0.002 shows a rule used by Kingsbury for standard duty journal bearings. In order that the other data may be interpreted with reference to the clearance ratio η/a, reference values of it are given from 0.0005 to 0.004. If clearances are chosen from these curves, they must, for best results, be supplemented by a suitable oil.

10. SHAFT DEFLECTIONS AND BEARING PERFORMANCE

Shaft deflections within journal bearings, which may be considerable when compared with the thickness of the oil film, should be investigated, particularly with long spans between bearings and with relatively slender shafts. For the purpose of determining shaft deflections and the general direction of journal center lines with respect to the bearings, loads may be assumed concentrated at the midpoint of the bearing. To study oil film shape in a self-aligning bearing, or where shaft deflection is so little out of line as not to require self-aligning bearings, bearing reaction may be assumed uniformly distributed.

As a first approximation it may be assumed that all the deflection occurs in the shaft, the supporting framework of the machine being relatively stiff. The bearings, if rigid, therefore remain aligned while the shaft is subject to deflection. Misalignment of journal and bearing is the product of the slope of the deflection curve and the length of the bearing. The general method of calculating deflections and slopes of shafts subject to bending is explained in Section 8, Article 2, p. 8-06. If the deflection is excessive relative to the oil film thickness, it is necessary to provide a self-aligning bearing. Even here the shaft may become slightly curved within the bearing due to the distributed load, and should be checked.

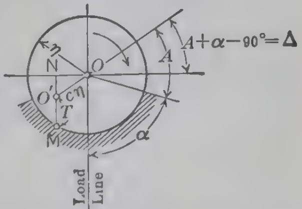

FIG. 88. Shaft deflection and shift of shaft center.

In calculating shaft deflection in a bearing, the position of the center of the shaft, when running, is important. It shifts to the point O' (Fig. 88) within the clearance circle of radius η. The plane of shaft deflection cuts this circle at M, which is the point at which the deflected shaft will make contact with the bearing, assuming that the latter does not deflect. The following relations (Fig. 88) hold: Let $(A + \alpha - 90°) = \Delta$. Then $\overline{ON} = c\eta \cos \Delta$; $MN = \sqrt{\eta^2 - \overline{ON}^2}$; $TO' = MN - c\eta \sin \Delta$. The deflection should be compared with distance $O'M$, and should not be an unreasonable percentage, say 30%, of $O'M$. The shaft usually should be examined for both strength and stiffness.

11. CONSTRUCTION AND STANDARDIZATION OF THRUST BEARINGS

THE THRUST PROBLEM. More or less axial load is encountered with every vertical shaft. With horizontal shafts, when there is no thrust load, only shaft shoulders are needed to hold the machine parts in proper axial relation.

Heavy horizontal loads are encountered in unbalanced centrifugal pumps and steam turbines, in marine propeller shafts, in industrial machines, and in some machine tools. When thrust loads are encountered at very low speed, the wear and the power lost in friction often are ignored and very inefficient bearings used, although it is better practice to use pivoted shoe thrust bearings and heavy oil, or to use rolling contact bearings. With relatively high speeds and large shafts, as for marine propellers, the power loss is important, and efficient durable thrust bearings are used. For very high speeds with heavy thrust loads, as in steam turbines, the thrust bearing must also be efficient and durable.

Light Horizontal Loads. Horizontal shafts, with little or no thrust load, often require close control of endwise position. This may be done by a collar on the shaft end as in Fig. 89. One collar in one bearing mounting then controls end play. Using the shaft shoulder, as in Fig. 81, requires two bearing mountings. See Thrust Bearing Design and Construction below.

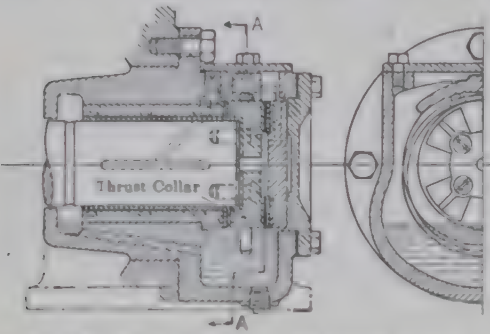

Fig. 89. Ring-oiled journal and thrust bearing.

Vertical Loads. A vertical shaft in a machine always has a thrust load, because of the weight of the machine elements that in a horizontal shaft would be carried by journal bearings. However, a vertical shaft has no side loads on its journals except those produced by the operation of the machine itself. The thrust load on a vertical shaft may be either increased or reduced by loads produced by operation of the machine. Thus, in a hydroelectric generating unit or a vertical centrifugal pump, hydraulic thrust in the runner may add to the load resulting from the weight of the revolving parts. The importance of the thrust problem depends on the combination of load and speed.

THRUST BEARING DESIGN. Thrust bearings may be divided into two main groups, viz., imperfectly lubricated and perfectly lubricated. The degrees of imperfection or perfection will vary. Among bearings that are perfectly lubricated, a bearing of one design may run with several times more friction than another, under otherwise identical operating conditions, and with no metallic contact of bearing faces during operation. Similarly, with imperfect lubrication, some bearings will run with higher friction than others, with the same oil, load, and speed conditions, but with more or less metallic contact of the bearing faces always present.

IMPERFECTLY LUBRICATED THRUST BEARINGS. Imperfect lubrication implies lack of provision for the functioning of adequate wedge-shaped films rather than lack of lubricant. See Perfect Lubrication, p. 12-03. For very low speed, heavy oils and hardness of bearing materials have been relied on to keep the rate of wear within reasonable limits. Such bearings should be placed in oil baths, if possible, so that lubricant may be continuously available. Grooving may be designed to keep oil from wasting or to produce circulation that will continually change the oil on the bearing faces.

Vertical Shafts. For this service the plain pivot, the multiple-disk-supported pivot, the plain ring thrust, the washer-supported ring thrust (Figs. 90 to 93) are used. The grooves in these bearings, if submerged in oil, should be carefully formed, usually in the upward faces, and with rounded edges, as in Fig. 94, in the harder surface. If oil is present

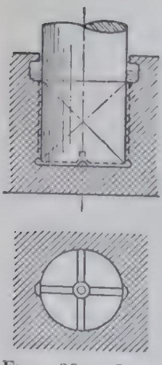

Fig. 90. Plain pivot thrust bearing.

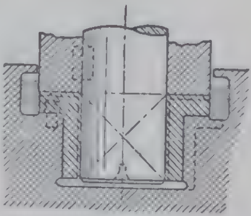

Fig. 92. Plain ring thrust bearing.

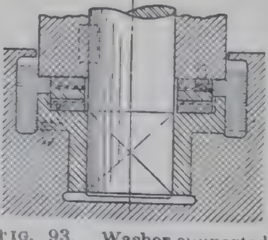

Fig. 93. Washer-supported ring thrust bearing.

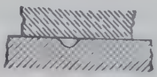

Fig. 94. Form of oil groove.

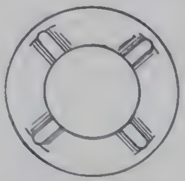

Fig. 95. Arrangement of groove in thrust washer.

in only minute quantities, grooves should be in the downward face. Further improvement can be made by slightly tapering the grooved bearing face for a distance at least equal to the width of the oil groove, on each side of the groove, but using not more than half the total surface for grooves and tapers. Two to four oil grooves usually are enough. For large diameters, or areas where radial width is relatively small compared with the circumference, more grooves may be used. The size of the groove will vary, increasing with size of the bearing, sluggishness of the lubricant, and speed of rotation. If an oil bath cannot be used, it is best to stop the grooves short of the circumference of the disk or washer and feed oil to the grooves from the center outward. (See Fig. 95.)

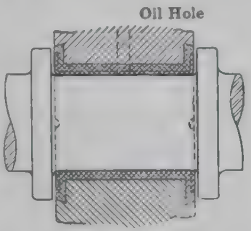

FIG. 96. Bearing to take light thrust in two directions.

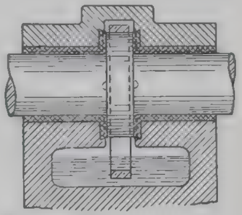

FIG. 97. Ring-oiled two-direction bearing for light thrust load.

Horizontal Shafts. Conditions usually are quite different from those of vertical shafts. An oil bath is less easily provided. Also, because of end play, it is difficult to prevent oil leaking away from the thrust surface, especially when thrust action is intermittent. For a simple construction like Fig. 96, thrust face grooves may be most easily cut in the stationary bearing face, although the harder face is preferable. Grooves should stop short of the outer diameter of the thrust collar. Sometimes a thrust collar, integral with or fastened to the shaft, is placed between two short journal bearings whose adjacent sides are enlarged to present reasonable thrust surfaces to the collar. If of sufficient diameter, this collar may be used to lubricate all bearing surfaces from a well below the shaft. Otherwise a ring may be used as in Fig. 97.

For data on friction coefficients of imperfectly lubricated thrust bearings, see p. 7-28. In such bearings the coefficient will, if bearing is adequately oiled, vary from 0.20 downward to about 0.02. This lower value would be considered very high for a perfectly lubricated bearing surface.

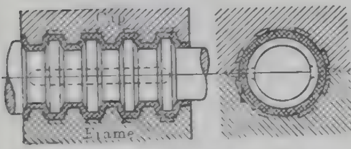

FIG. 98. Multiple-collar bearing sometimes used in woodworking machinery to position spindle.

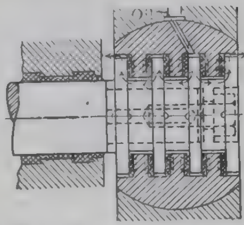

FIG. 99. Multi-collar thrust bearing for light loads.

Multi-collar thrust bearings are used in several forms, more or less well made. In woodworking machinery, a bearing-metal lining is poured into the frame and cap, around a grooved shaft (Fig. 98). Oil is best applied at the sides. Such a bearing if lightly loaded, and not too tightly clamped on the shaft, may serve as a combined journal and thrust bearing, but it is not considered good practice. Sometimes the cap of such a bearing is made axially adjustable for control of end play. Figure 99 shows a multi-collar bearing used only to carry light thrust loads. It is adjacent to an adequate journal bearing. Oil under pressure may be applied as marked, and caused to flow through suitable grooves back and forth across the faces of the collars. If carefully made, and when oil grooves are properly designed with adjacent surfaces properly beveled, these bearings can carry moderate loads even at high speed.

One serious difficulty with all multi-collar thrust bearings is the inequality of distribution of load among the collars. To help overcome this in large bearings for marine service, inverted U-shaped elements, called horseshoes, with soft metal faces, are placed between the shaft collars. Sometimes grease is used for lubrication, but usually oil is supplied from a bath below the shaft into which the collars dip. The shoes sometimes are water-cooled by passages, but for high-speed bearings a water coil usually is placed in the bath below the collars. Horseshoes in marine practice are loaded at 30 to 70 psi. They now are seldom used, because more efficient and more durable types of bearings are available that operate with about one-tenth the power loss. (See pp. 12-56 to 12-60.)

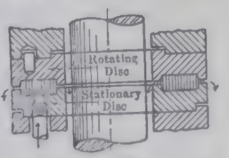

FIG. 100. Oil pressure thrust bearing.

THE OIL PRESSURE THRUST BEARING employs two disks constructed as in Fig. 100. Oil is pumped under high pressure into the stationary disk at a definite rate, lifting the upper or rotating disk until oil discharge rate equals supply rate. Accumulators are required to protect against stoppage of the pumps. Rollers sometimes are provided to prevent contact of narrow faces of disks when oil supply fails. If the disks are permitted to rub they will "flash" and be damaged. Friction in the bearing itself is very low, but considerable power is required to drive the pumps.

PERFECTLY LUBRICATED THRUST BEARINGS. See Perfect Lubrication, p. 12-03 for a discussion of the principles underlying the formation of the tapered oil film. Such films, in various forms, exist between the bearing faces of the thrust bearings described below.

The fixed-wedge film type of thrust bearing was suggested in 1888 by Professor Archibald Barr, when discussing Beauchamp Tower's then recent tests on plain collar thrust bearings. It is obvious that part of the thrust bearing face must be flat to permit the collar to start and stop under load without undue concentration of pressure. The wedge-shaped film in a bearing of this kind is unable to lift its load until a fair speed is attained. Conversely, it is likely to stop suddenly when slowing down. The fixed wedge may be combined with a flat surface, by using alternate bevels and flats with a supply groove *G* at the thick end of the bevel, in the direction of motion (Fig. 101). This construction is used in the Gibbs thrust bearing, built by S. Morgan Smith Company, York, Pa. Bearing pressures range from 200 to 300 psi.

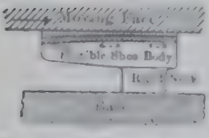

Fig. 104. Thrust bearing with flexible shoe on rigid neck.

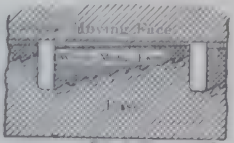

Sperry Gyroscope Co.

Fig. 105. Restrained wedge-film bearing.

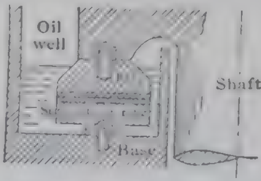

Fig. 106. Radial section of thrust bearing indicating radial tilting.

A characteristic of these bearings is that the slope of the wedge remains constant for all conditions of load, speed, oil viscosity, and temperature for a given bearing. The film thickness, however, will vary automatically as these conditions change, provided the speed is great enough to separate the flat faces.

The free-wedge film (Fig. 102) type of thrust bearing (see Pivoted Shoe Bearings, p. 12-57) was conceived, constructed, and tested in 1896 by Professor Albert Kingsbury. A parallel, but independent, development of the similar Michell thrust bearing has taken place in England. The bearing members (shoes) in this type are tiltably mounted, and are free to form automatically the most efficient natural oil film required by each different combination of load, speed, viscosity, and temperature to which the bearing is subjected.

The restrained-wedge film type of thrust bearing appears in several forms. In this type the elements forming the films are not fully free, but do respond, in a limited degree, to change of load, speed, viscosity, and temperature. One of these (Fig. 103) was invented by H. G. Reist about 1915. Its stationary element is a babbitted, relatively thin, steel ring, with one radial gap, mounted on many small stiff precompressed springs. Radial grooves are cut in both the opposing bearing faces to supply cool oil to the bearing faces. Both stationary and rotating grooves are chamfered to direct the oil between the surfaces. In the event of misalignment, the flexible support automatically deflects to equalize the pressure distribution over the entire bearing.

Figure 104 shows a second form of restrained-wedge film bearing, inventor unknown. Restraint of wedge film formation is imposed by the rigid neck and the stiff portions of the adjacent shoe body. This is an integral structure. The bearing faces of the shoe bodies are finished flat. The flexing of the overhung portion takes place under the pressures incident to the formation of the film.

A third and rather unusual restrained wedge film, invented by Elmer D. Sperry, is shown in Fig. 105. The supporting base is faced with bearing metal of thickness that varies considerably. Babbitt metal has a coefficient of elasticity much greater than iron or steel. Hence if the thickness is greater where the pressures are lower, a wedge-shaped film may be formed.

Radial tiltability may be given to relatively thick bearing rings by applying the load to their backs through annular supporting ribs. (See Fig. 106.) Also the lower ring may be made in separate segments that have freedom only for radial tilting, in which case the ribs supporting the segments may be tangential. Such elements may have fixed bevel bearing faces or flexible leading portions, as already described.

Film Forms. When the relative motion is circular, instead of straight line, the flat-faced wedge film is not geometrically a flat wedge in the developed section of the path of relative motion but is a sine curve wedge, as in journal bearings. There also are changes in film shape due to elasticity of materials, and to temperature variations. Thrust bearing films, therefore, usually are of a composite nature. Occasionally a composite form is purposely given the film, as when beveling is added to the leading or trailing portions of the bearing face of the freely tilting shoe. A variable composite film appears in the Reist bearing (Fig. 103), in which both bearing faces are provided with oil grooves. The double grooving tends alternately to build up and to break down the pressure in the films, but it helps the radial flow of oil across the bearing faces.

CONSTRUCTION DETAILS. Reversible Bearings. In general a thrust bearing may be made suitable for both directions of rotation, i.e., reversible, by making its supporting feature symmetrical with respect to the bearing face segments or grooves. For example, the free-wedge type may have its shoes supported in the middle, and it loses little efficiency thereby. The fixed-wedge type requires the provision of an additional beveled portion, tapered in the opposite direction. When the limit of dead load supportable by the flat parallel portion of the bearing face is reached, the reversible fixed-wedge bearing area would have to be larger than if made for one direction only.

ALIGNING AND EQUALIZING MEANS FOR THRUST BEARINGS. When the machine is so accurately made that alignment of shafting is perfect within the limits of the film thicknesses in the bearings and the elasticity of the component parts, no aligning means need be provided. This also is true when the bearings are so placed with respect to the machine frame that the slight elasticity of the frame itself enables the bearings to preserve their proper alignment. However, it often is desirable to provide some aligning means within the thrust bearing, and the methods cited below are employed.

The design of aligning means should be governed by the misalignment to be corrected, as initial, subsequent, or continuous or rapidly recurring. The durability of the aligning means, therefore, is an important consideration in the selection of a thrust bearing. Special forms have been devised for such service as gyro-stabilizers and for thrust collars that are out of square with the shaft.

The spherical washer (Fig. 109) is the commonest form and has several advantages, one of which is ruggedness. When used with three freely tilting shoes it tends to equalize the load distribution among them. For best efficiency, the mean angle of the spherical faces should be about 45°. Even so, when once well loaded, an eccentricity of the load equal to more than half the projected radius to the mean zone of the spherical fit is required before slipping will take place. Hence, this method of equalizing or aligning is not sensitively responsive to variations in alignment under load.

Adjustable Bearings. When freely tilting shoes are mounted on jack screws, the latter may be used for initial setting of height, alignment, and equalization of load, but are not useful for preserving alignment when the supporting structure shifts.

Elastic support is an approximate aligning means, and also an approximate equalizing means for various portions of a bearing when little correction need be made. With the stiff springs necessarily employed, careful preliminary setting of the thrust deck is essential. Means to prevent or control vibration must be employed.

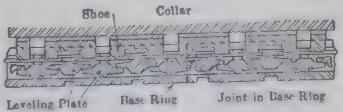

Fig. 107. Equalizing supports of Kingsbury thrust bearing.

Equalizing Supports. Systems of rocking levers were introduced by Kingsbury for initial alignment and equalization. They continue effective, even in the presence of considerable subsequent displacement of the thrust deck. (See Fig. 107.) This form has been adapted, with roller contacts, to very large hydroelectric bearings.

PIVOTED SHOE THRUST BEARINGS. Kingsbury began to standardize pivoted shoe thrust bearings when he applied the adjustable type to vertical shafted hydroelectric units 1912 to 1915. This type ran to large sizes (e.g., Fig. 108) and did not lend itself readily to small diameters. The application of his self-aligning and equalizing thrust bearings to the geared turbine drives of ships led to the Kingsbury standards listed in Table 17

For capacity see Table 10, p. 12–34.

Horizontal Equalizing and Self-aligning Types. Because of the relatively recent development of the Kingsbury pivoted shoe oil film bearings their standardization is not widely known.

Internal Parts. The self-aligning and equalizing types of Kingsbury thrust bearings consist mainly of the shoes and their supporting structures shown in Figs. 109 and 110.

The overall dimensions of these 3-shoe and 6-shoe elements are made the same for interchangeability. (See Table 17.) These elements may be used either horizontally or vertically, but usually they rely on a surrounding wall of the mounting to hold the shoes radially in place.

Commonly used combinations of these elements are (1) 3-shoe base and 6-shoe base with thrust collar between, (2) double 3-shoe base with collar between, (3) double 6-shoe bearing for two-way thrust with separate collar (see Fig. 111), and (4) double 6-shoe bearing with collar integral with shaft (see Fig. 112). In this construction the 6-shoe bases are made in halves.

Fig. 113. Spherical thrust bearing.

SPHERICAL THRUST BEARING (Fig. 113) performs in one unit the functions of both flat thrust and guide bearing. Six pivoted shoes *T* are seated in the solid base ring *B*, the shoe faces being concave against the spherical-faced runner *R*. The bearing will sustain a radial load of about 15% of the downward load, and, unlike a cylindrical guide bearing, it requires no radial running clearance. The shaft, therefore, will run accurately centered. For high speeds, an air seal ring *C* around the runner minimizes foaming. A narrow bronze bushing *S* surrounding, and loose on, the thrust block hub *H* holds the parts together in handling. For temporary radial overloads, or lifting of the shaft, an auxiliary guide bearing may be applied above the spherical thrust bearing. The guide bearing shoes then are bored with a larger running clearance, and act only if the shaft lifts. Four 30-in. bearings of this type, operating at 500 rpm, are used in condensers at the Leaside Station, Toronto, Ont.

Fig. 114. Marine type automatically lubricated thrust bearing.

MARINE TYPE AUTOMATICALLY LUBRICATED THRUST MOUNTING (Fig 114) is commonly used with Kingsbury thrust bearings abaft ship propulsion machinery, where the shaft diameter is large and the full area of the thrust collar is not required to carry the load. Two thrust shoes in each end of the mounting are adjusted by jack screws and hardened thrust pins. The adjacent journal bearing has a removable split shell. End closures commonly are of nonwearing types. Oil lifted by the thrust collar is directed to the bearing surfaces.

LUBRICANTS

By Paul G. Exline

A lubricant is a material interposed between two relatively moving machine elements to reduce friction and wear. Liquid, plastic, and solid materials are used as lubricants although sound design requires the application of liquid lubricants wherever possible.

12. TYPES OF LUBRICANTS

MINERAL OILS. Mineral oils are by far the most commonly used liquid lubricants, primarily because of their cheapness and stability. Their current consumption is at the rate of approximately 2.25 billion gallons per year. They are complex mixtures of paraffinic, naphthenic, aromatic, and unsaturated hydrocarbons distinguished from other crude oil fractions by their viscosity.

In general, three classes of distillates are made in separating the lubricating cuts from the crude oil: (1) Wax distillates, dewaxable by filter-pressing, from which neutrals and paraffin oils are derived. (2) Unpressable distillates, which are also noncentrifugal and must be dewaxed by the use of solvents. (3) Overhead cylinder stocks, representing the last high-boiling constituents of a crude oil except a usually asphaltic residuum.

Residual materials made are usually of two kinds: (1) Long residua, including everything in the crude oil after the wax distillates have been removed. (2) Cylinder stocks, including everything after the unpressable distillates have been taken overhead. Both long residua and cylinder stocks are dewaxed by centrifuging.

By redistillation, refining, and blending of these five type stocks, lubricating oils are produced in wide range, from spindle oils hardly more viscous than kerosene to highly viscous and heat-resistant airplane engine and steam cylinder oils.

Modern methods provide the refiner with greater independence of the crude oils than was formerly true, since certain constituents can be removed from a naphthenic stock leaving a material which approximates that derived from an intermediate base crude. Likewise a product can be obtained from an intermediate-base oil having the properties of a high-grade paraffinic material.

Compounding of mineral oils is commonly practiced to secure properties of the finished product not obtainable by blending and refining the different stocks. Vegetable and animal oils are added to obtain greater lubricating action where conditions of boundary lubrication may be met. Instead of 10 to 20% of the fixed oils, smaller percentages of the fatty acids may be used. In many cases small quantities of synthetic addition agents may be used to produce specific effects such as to retard oxidation, to provide detergency, or to control emulsification.

ANIMAL AND VEGETABLE OILS. Animal, vegetable, and fish oils were among the earliest known lubricants and are still widely used both alone and as compounding agents. They are commonly referred to as fixed oils because of their tendency to decompose before distillation. Their lubricating properties are due to varying percentages of glycerides of the fatty acids: linoleic, oleic, palmitic, stearic, and others.

Typical oils of this class in common usage are castor, peanut, palm, and rapeseed of the vegetable oils, neat-foot, lard, and tallow oils of animal origin, and whale and sperm oils. Sperm oil differs from the others in that the fatty acids are in combination with alcohol rather than glycerol.

SYNTHETIC LIQUIDS. During the early 1940's impetus was given to the development of certain synthetic lubricants.

One group of the synthetic liquids are the polyorganosiloxanes or silicone fluids. They are similar in molecular structure to the mineral oil hydrocarbons, but certain of the carbon atoms are replaced by silicon atoms. They can be manufactured in a wide range of viscosities and with an unusually flat viscosity-temperature curve. (See Fig. 1.) The value of the silicones as lubricants is more than usually dependent upon the bearing materials, and their use should be referred to the manufacturer. Their stability at high temperatures has enabled them to be used as journal bearing lubricants at 300 to 375 F for long periods of time. Their low pour point, less than − 100 F in some of the low viscosity grades, permits their use at lower temperatures than the temperatures at which mineral oils can be used.

Other synthetic lubricants of interest are oils obtained by the Fischer Tropsch process, the polyglycal ethers, and the aliphatic diester oils. Some of the synthetics have unusually small temperature coefficients of viscosity and others extremely low freezing points. In general, their high cost limits their application to places where mineral oils cannot be used.

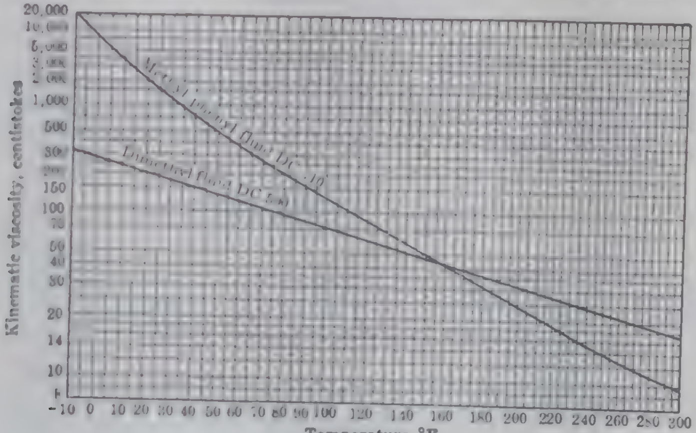

FIG. 1. Viscosity-temperature relationships of two silicone fluids.

MISCELLANEOUS FLUIDS. Various fluids have been used as lubricants in special cases, such as water for stern tube bearings and air for high-speed centrifuge bearings. In certain chemical processes it is desirable to use the process liquid as the lubricant. In such cases the compatibility of the lubricant with the bearing materials should be very carefully considered.

GREASES. Greases are usually suspensions or gels of metallic soaps dispersed in a lubricating liquid. The calcium and sodium soaps of the common fatty acids are largely used, although aluminum, lead, and lithium soaps are employed to a lesser degree. The consistency of greases varies from nearly liquid to the hard blocks used for locomotive crosshead lubrication, depending upon kind and percentage of the soap content and viscosity of the base oil. In general, a grease is used for relatively slow speed systems which at the same time offer difficulty in the retention of liquid lubricants, or in systems where high temperatures are encountered.

Synthetic resins or even rubber may be added to greases to increase their stickiness or retentivity.

SOLID LUBRICANTS. The most commonly used solid lubricant is graphite, both in powdered and colloidal form. Its stability at elevated temperatures and its low coefficient of friction make it desirable where organic materials cannot be applied. Graphite is also used as an additive to both oils and greases. Soapstone, talc, and waxes are used as lubricants for certain applications.

Under conditions of extremely high pressures, tungsten disulfide, molybdenum disulfide, and silver sulfate have been found to be effective solid lubricants.

13. PROPERTIES OF LUBRICANTS

Under conditions of thick film lubrication, the viscosity of a lubricant is its only important property. Since many applications of lubricants are where thick film conditions do not exist, and since even bearings designed for thick film lubrication will occasionally operate in the thin film or boundary condition, the oiliness of a lubricant becomes of importance. As a lubricant is quite often required to operate in a system for long periods of time and occasionally at elevated temperatures, its oxidation and its thermal stability are of interest. Other properties of lubricants such as acidity, saponification number, color, cloud and pour points, sedimentation, flash and fire points, emulsification, iodine number, and specific gravity are commonly determined by the refinery laboratories as specification tests to control the uniformity of the products. Their value in determining the relative worth of lubricants is minor or nonexistent.

VISCOSITY. The viscosity of a liquid is defined as the ratio of the shearing stress to the rate of shear. In the cgs system the unit of viscosity is the poise or one dyne sec/cm². The centipoise or 0.01 poise is more frequently used because of its size. One centipoise or 0.01 dyne sec/cm² = 2.09×10^{-5} lb sec/ft² = 1.45×10^{-7} lb sec/in.² (Reyn) = 2.42×10^{-9} lb min/in.² Because certain viscometers measure the ratio of viscosity to specific gravity, this term has been called the stoke, and one-hundredth its value the centistoke. It is expressed in cgs units.

It is common practice in the American petroleum industry to express viscosity in Saybolt universal seconds (SUS). This is the time of efflux, in seconds, necessary for 60 ml of the liquid to drain through a tubular orifice in the bottom of a vessel whose dimensions and construction are rigidly specified. As it is impossible to use Saybolt seconds in numerical computations of bearing performance, they must first be converted to absolute units (see Table 1).

Table 1. Values for Converting Saybolt Viscosity to Kinematic Viscosity

Kinematic Viscosity, centistokes	Equivalent SUS at 100 F	Equivalent SUS at 210 F
2	32.6	32.8
2.5	34.4	34.6
3	36.0	36.3
3.5	37.6	37.9
4	39.1	39.4
4.5	40.7	41.0
5	42.3	42.6
6	45.5	45.8
7	48.7	49.0
8	52.0	52.4
9	55.4	55.8
10	58.8	59.2
15	77.2	77.7
20	97.5	98.2
25	118.9	119.7
30	140.9	141.9
40	185.7	187.0
50	231.4	233.0
60	277.4	279.3
70	323.4	325.7
Over 70	SUS = CS × 4.620 CS = SUS × 0.2165	SUS = CS × 4.652 CS = SUS × 0.2150

Note. To obtain SUS equivalent to a kinematic viscosity at *t* F, multiply the equivalent SUS at 100 F by $1 + (t - 100) \times 6.4 \times 10^{-5}$.

Since the Saybolt viscometer is insensitive to differences in viscosity in the low viscosity range, readings below 32 sec are not taken. The practice is becoming widespread of using the modified Ostwald viscometer, which gives results directly in kinematic viscosity. Unfortunately, oil companies still convert these values to SUS for their published data, so that it is necessary to convert the data back to absolute viscosity before they can be used.

Mineral oils decrease rapidly in viscosity with increase in temperature. This decrease may be from 0.6 to 6.0% per °F. The most convenient method of expressing the variation of viscosity of lubricating oil with temperature is the ASTM chart, which is based on an assumed equation that agrees very well with results of tests and gives a straight line graph when a function of viscosity is plotted against a function of temperature. The ASTM chart is available with temperature in °F as the abscissa and either kinematic viscosity in centistokes or SUS as the ordinate. With this chart, a straight line can be drawn through two points, indicating the viscosity at two temperatures, so that the viscosity at any temperature within a reasonable range can be determined.

The equation on which the ASTM chart is based is

$$\log_{10} \log_{10} (\nu + 0.8) = n \log_{10} T + C$$

where ν is the kinematic viscosity, centistokes; T the absolute temperature, Fahrenheit degrees; and n and C are constants for any given oil. This expression is very unwieldy where it is necessary to express the viscosity as a function of temperature in mathematical analysis. For this purpose, a much more convenient equation is based on the formula of Slotte

$$\mu = at^{-b}$$

where μ is the absolute viscosity, centipoise; t the temperature, °F; and a and b are constants for any given oil. If the constants are evaluated for measurements made at 100 and 210 F, the equation is quite satisfactory for the range 60 to 300 F.

Dean and Davis have devised a system of rating lubricating oils by means of an arbitrarily determined viscosity index (VI) based on a change of SUS for a given temperature change in °F. Two groups of mineral oils were used for establishing this rating; one group was from the Pennsylvania fields, and the other from the Gulf Coast. The Pennsylvania oils were given a rating of 100 VI, and the Gulf Coast oils a rating of zero VI, and a method was set up for determining the VI of any other oil based on its Saybolt viscosity at 100 F and at 210 F. This irrational system gives a somewhat deceptively large numerical change for what are actually relatively small viscosity changes. Application of VI numbers to some of the newer synthetics having quite low changes of viscosity with temperature are particularly confusing and misleading.

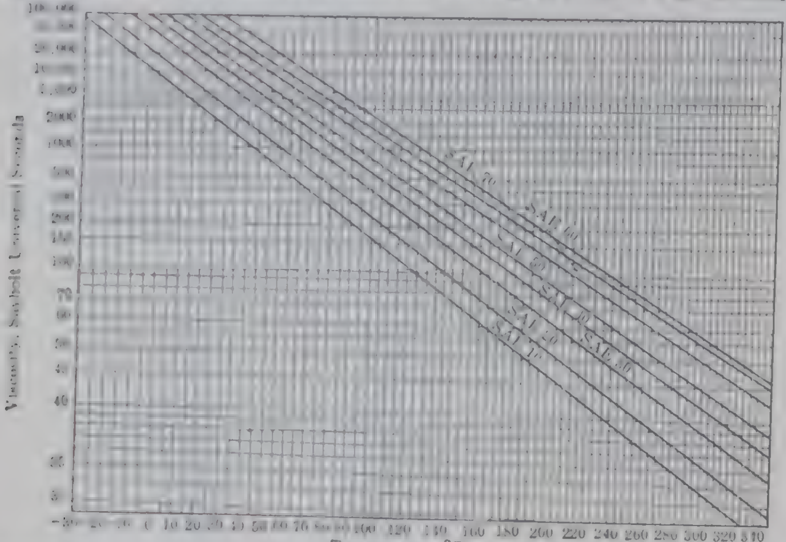

FIG. 2. Viscosity-temperature relationship of SAE grades of petroleum oils having 100 viscosity index

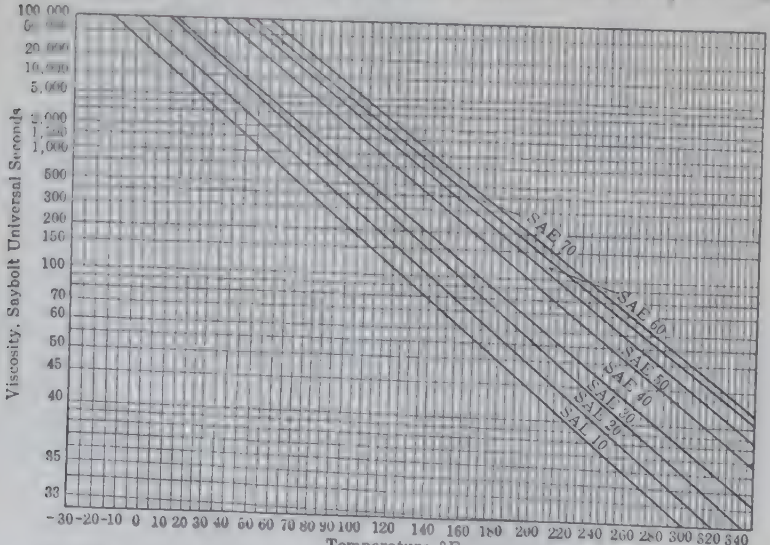

FIG. 3. Viscosity-temperature relationship of SAE viscosity grades of zero viscosity index.

The Society of Automotive Engineers has developed a numerical system for expressing the different viscosity grades of lubricants. Although some overlapping is encountered, it provides a useful method of selecting viscosity within commercial tolerances. Figures 2 and 3 show the viscosity ranges for the different SAE numbers for a viscosity index of 100 and 0, respectively. Figure 4 shows the ratios of kinematic viscosities at 100 and 210 F as a function of VI for oils of various viscosities at 210 F.

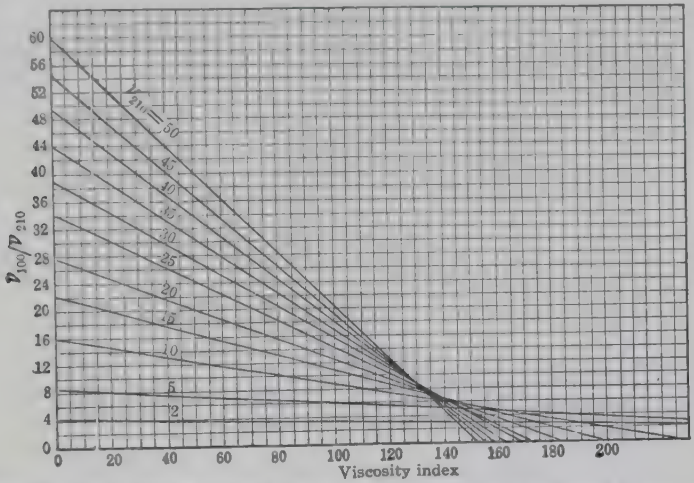

FIG. 4. Viscosity ratios versus viscosity index, at various viscosities expressed in centistokes. ν_{100} = viscosity at 100 F, ν_{210} = viscosity at 210 F.

SPECIFIC GRAVITY. The density or specific gravity of a petroleum oil has no correlation with its lubricating value. It is generally included in the description of a lubricant and is useful in converting from kinematic viscosity to absolute viscosity. Specific gravity is generally given as the ratio of the density of the lubricant at 60 F to the density of water at 60 F. In the petroleum industry, the term "API gravity" is preferred to specific gravity and is expressed in terms of API degrees. The relation between the two is

$$°\text{API} = \frac{141.5}{\text{Specific gravity } 60/60 \text{ F}} - 131.5$$

or

$$\text{Specific gravity } 60/60 \text{ F} = \frac{141.5}{°\text{API} + 131.5}$$

Experimental data on the expansion of petroleum oils indicate that their coefficient of expansion is a function of the density (at a fixed temperature) only. This permits a fortunate simplification of all density corrections, as specification of the specific gravity at a single temperature is sufficient for its calculation at any other temperature. Figure 5 shows the coefficient of expansion K plotted as a function of the specific gravity 60/60 F. The specific gravity, S_t, at any temperature t F can be computed by this equation:

$$S_t = S_{60}(1 - K[t - 60])$$

SPECIFIC HEAT. A knowledge of the specific heat of a lubricant is necessary in computing heat balances in force-fed bearings. The data on petroleum hydrocarbons have been summarized in the following equation, which is accurate to within 5%.

$$C = \frac{1}{S}(0.388 + 0.00045t)$$

where C = specific heat Btu/lb/ F; S = specific gravity 60/60 F; and t = temperature F.

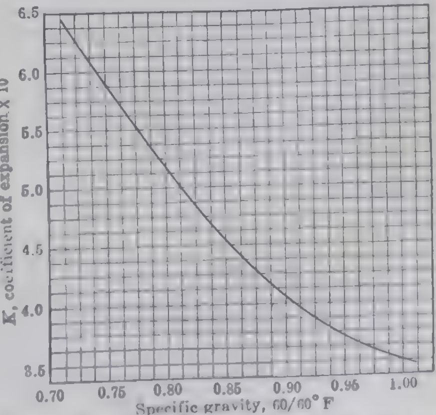

FIG. 5. Coefficient of expansion of petroleum oils versus specific gravity at 60°/60° F.

SELECTION OF MINERAL LUBRICANTS. Mineral lubricants are selected principally on the basis of their viscosity and their temperature coefficient of viscosity. Many cases arise where other properties become of importance, such as oxidation stability, oiliness, and film strength. Not only are these properties poorly susceptible of definition but they are also not a function of the lubricant alone, being dependent upon the conditions of use and the materials in contact. There is not nearly enough reliable information now available about test methods to permit writing workable oil-purchase specifications that would within themselves, without performance tests, serve as a reliable guide in the selection of lubricants. Even though a lubricant is found to perform satisfactorily in a given application, it does not necessarily follow that other lubricants will be equally satisfactory when purchased on specifications based on its descriptive tests. Purchase specifications should be prepared with the assistance of a competent oil chemist, and wherever possible should be based on performance tests.

ROLLING BEARINGS

By Gunnar Palmgren and Bryce Ruley

Ball or roller bearings support a loaded moving part on a set of hardened steel rolling elements. These rolling elements usually roll between two smooth hardened steel rings, although in some cases the rolling elements may roll directly on the shaft or in the housing bore. Normally, a cage or a separator is used to keep the rolling elements properly spaced about the bearing pitch circumference. All parts are manufactured to very close tolerances and to exacting material specifications.

Standard rolling bearings are manufactured as interchangeable units and can be quickly obtained and inserted as a unit if their replacement is necessary. Ball and roller bearings have the low friction characteristic of rolling motion, this friction being only slightly greater when starting than under uniform speed of rotation. Anti-friction bearings, especially roller bearings, are relatively insensitive to moderate overloads or shock loads, their life being calculated on the basis of mean effective load rather than maximum load.

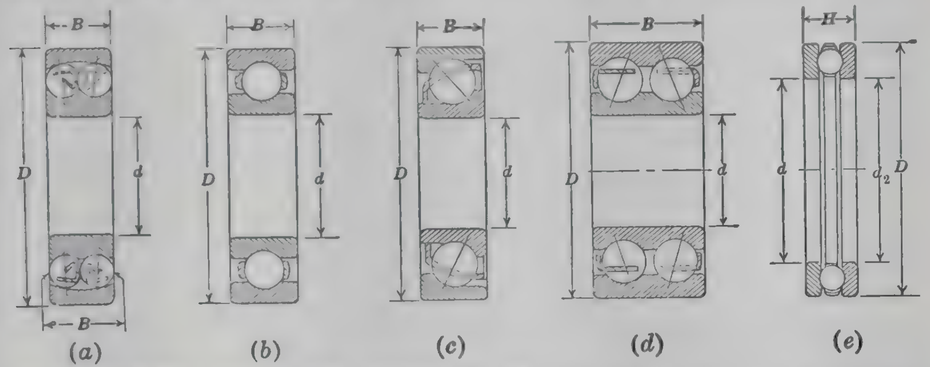
Although in rolling bearings sliding motion is essentially replaced by rolling motion, some miscellaneous sliding does occur (e.g., between balls and cage, between rollers and guide flange, etc.). Some lubrication is therefore necessary, but in most cases the lubrication needs of rolling bearings are moderate compared to the needs of other bearing types.

14. BEARING TYPES

Of the large number of bearing types which have been invented, only a few types, which combine ease of manufacture with some inherent advantage in practice, have survived as modern standard bearings. Some modern types of ball bearings are shown in Fig. 1 and some modern roller bearing types in Fig. 2.

Selection of the proper bearing for a given application may be a difficult problem, requiring the advice of a qualified bearing engineer, but some general principles can be set down.

Ball bearings are usually the most economical choice for the smaller sizes and lighter loads; roller bearings are usually more satisfactory for the larger sizes and heavier loads. Roller bearings have considerably less sensitivity to shock loading than ball bearings. Most bearings lose capacity if misaligned any measurable amount, but self-aligning bearings (spherical roller bearings, Fig. 2*d*, spherical roller thrust bearings, Fig. 2*e*, and self-aligning ball bearings, Fig. 1*a*) can take two or three degrees of misalignment without loss in capacity.



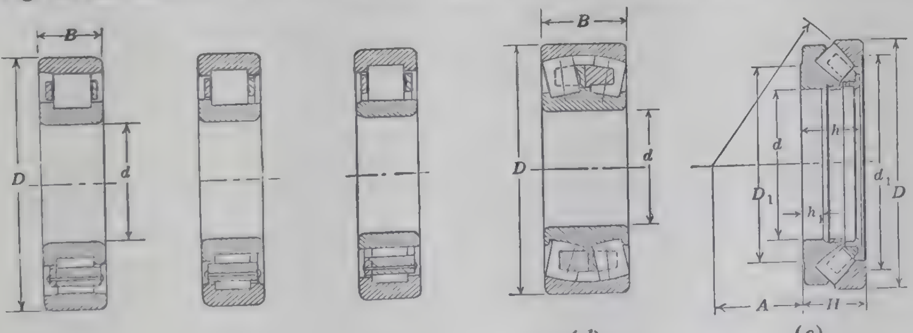
(*a*) (*b*) (*c*) (*d*) (*e*)

FIG. 1. Types of ball bearings: (*a*) self-aligning; (*b*) deep-groove; (*c*) angular contact; (*d*) double-row; (*e*) thrust.

A major influence on bearing choice is the direction and magnitude of the load. **Cylindrical roller bearings** (Fig. 2*a*,*b*,*c*), for example, are designed to carry radial loads, some of them being made without flanges on one ring so that they can carry no thrust load, whereas others are able to take the light thrust loads necessary to stabilize the shaft.

Self-aligning ball bearings (Fig 1*a*) are designed primarily to carry light and moderate radial loads but can carry some thrust load in either direction. **Deep-groove ball bearings** (Fig. 1*b*) and **double-row ball bearings** (Fig. 1*d*) are designed to carry light, medium, or heavy radial or combined loads. These bearings can carry substantial thrust loads but are not usually the best choice for pure thrust loads.

Angular contact ball bearings (Fig. 1*c*) are designed to carry thrust loads or combined loads which are predominantly thrust. They can carry radial loads if two of them are mounted opposed, but they are not recommended for the purpose. **Ball thrust bearings** (Fig. 1*e*) can carry pure thrust load only. Any radial load present must be carried by a separate radial bearing. Ball thrust bearings can carry fairly heavy thrust loads but their use is normally limited to low and medium speeds. For high-speed applications angular contact ball bearings are usually more satisfactory, even for pure thrust loads.



(*a*) (*b*) (*c*) (*d*) (*e*)

FIG. 2. Types of roller bearings: (*a*), (*b*), and (*c*) cylindrical; (*d*) spherical; (*e*) spherical thrust.

Spherical roller bearings (Fig. 2*d*) are a self-aligning type designed to carry medium or heavy radial or combined loads. Although spherical roller bearings can carry heavy thrust loads, a related type, the **spherical roller thrust bearing** (Fig. 2*e*), is usually a better choice if the load is pure thrust or if the radial component of load is always less than **two-thirds the thrust component.**

15. BEARING LIFE]

Selection of the bearing on an engineering basis has usually eliminated any chance of excessive or improper loading, and satisfactory operating conditions can be insured by adequate lubrication and by sealing against the entrance of corrosive or abrasive materials. Since failures from improper operating conditions can usually be prevented, they are not considered in determining the life of the bearing.

There is one type of failure, however, that is not preventable. Ultimately, if operating conditions are satisfactory, the bearing fails from a progressive fatigue flaking of the bearing raceways or rolling elements. The number of revolutions the bearing makes before the first evidence of fatigue can be detected is defined as the life of the individual bearing.

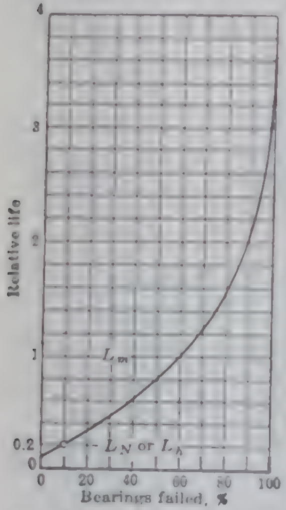


FIG. 3. Life dispersion of rolling bearings.

When a large number of bearings, of the same type and size, are run to fatigue failure under equal loads, a considerable dispersion is found in the individual lives as shown in Fig. 3. Since reliability is a major requirement for bearings in most applications, bearings are rated on the basis of the life which 90% of the bearings in a group will equal or exceed before fatigue failure. This is called the rated life or simply the life of the bearing. The average life of a bearing is approximately five times its rated life.

If two groups of bearings, of the same type and size, are run to fatigue failure, the first group under a load F_1 giving a rated life L_1 and the second group under a load F_2 giving a rated life L_2,

$$\frac{L_1}{L_2} = \left(\frac{F_2}{F_1}\right)^3 \tag{1}$$

This is sometimes referred to as the fundamental law and may be stated: *The rated life of a bearing varies inversely as the cube of the load.*

If the rated life for some given load is known, the rated life for any other load can be calculated by means of the fundamental law. A convenient reference load is the *dynamic reference capacity*, C, defined for radial bearings as that pure radial load which will give the bearing a rated life of one million revolutions (e.g., 500 hours at 33.3 rpm) when the bearing inner ring rotates relative to the direction of load. Similarly for thrust bearings, the dynamic reference capacity is defined as the pure thrust load which would give the bearing a rated life of one million revolutions. Numerical values of dynamic reference capacities are given in the bearing tables (Tables 5 to 13).

If a radial bearing is loaded by a thrust or combined load, or if the outer ring moves relative to the direction of load, the equivalent radial load under normal conditions (e.g., pure radial load and inner ring rotating relative to the load direction) is found by means of the relation

$$P = XF_r + YF_a \tag{2}$$

where P is the equivalent radial load under standard conditions, pounds: X is a rotation factor which depends on the bearing type and on which ring rotates relative to the load direction; Y is a thrust factor which depends on the bearing type and sometimes on the load; F_r is the radial component of load, pounds; F_a is the thrust component of load, pounds.

Numerical values of X are given in Table 1 for various bearing types and numerical values of Y are given in Tables 5 to 13.

Table 1. Rotation Factors

Bearing Type	X Factor for Rotating Inner Ring	X Factor for Rotating Outer Ring
Self-aligning ball bearing	1	1
Single row angular contact ball bearing	0.5 *	0.7 †
All other radial bearings	1	1.4

* If $P < F_r$, set $P = F_r$.
† If $P < 1.4F_r$, set $P = 1.4F_r$.

Most thrust bearings cannot carry any radial load. For those which can (e.g., spherical roller thrust bearings) the equivalent thrust load can be calculated from the equation

$$P_a = F_a + Y_a F_r \qquad (3)$$

where P_a is the equivalent thrust load, pounds; and Y_a is a rotation factor, which, for spherical roller thrust bearings, is 1.8 for inner ring rotation and 2.1 for outer ring rotation.

After the equivalent load has been calculated by eq. 2 or eq. 3, the rated life may be calculated by the fundamental law, eq. 1. In practice, however, this law is modified. Since the life in number of rotations can be expressed as a function of the life in hours and the speed in rpm, eq. 1 can be expressed as

$$C = \frac{f_h P}{f_n} \qquad (1a)$$

or

$$f_h = \frac{f_n C}{P} \qquad (1b)$$

where C = the dynamic reference capacity, pounds (see Tables 5 to 13); P = the equivalent radial (or equivalent thrust) load; f_n = a speed factor (found from scale 1, Fig. 4) = $\sqrt[3]{33.3/n}$; and f_h = a life factor (found from scale 2, Fig. 4) = $\sqrt[3]{L_h/500}$.

The following example illustrates the use of this method.

Example. What is the rated life in hours for a medium series deep-groove ball bearing (Fig. 1b) with a 50-mm bore under a radial load of 1000 lb and a thrust load of 500 lb at 600 rpm, if the inner ring rotates relative to the direction of load?

Since the bearing has a moderate load a Y factor of 1.2 can be assumed. Then the equivalent radial load at 750 rpm is found from eq. 2:

$$P = 1 \times 1000 + 1.2 \times 500 = 1600 \text{ lb}$$

Since the speed is known, the value of f_n can be read from scale 1. The value which corresponds to 750 rpm is $f_n = 0.354$. The value of C for this bearing is found from Table 6 to be 10,400 lb. Then, by eq. 1b,

$$f_h = \frac{0.354 \times 10{,}400}{1600} = 2.30$$

By scale 2, the rated life is found to be 6100 hours.

As an indication of the rated life desired in various types of machines, Table 2 may be used.

At times the load acting on the bearings is not constant. If the cyclic changes in the load are known and if the load cycle is not a multiple of the time necessary for the bearing to make one rotation, then the *mean effective load* can be found from the equation

$$P_m = \sqrt[3]{\frac{P_1^3 N_1 + P_2^3 N_2 + \cdots + P_n^3 N_n}{N_1 + N_2 + \cdots + N_n}} \qquad (4)$$

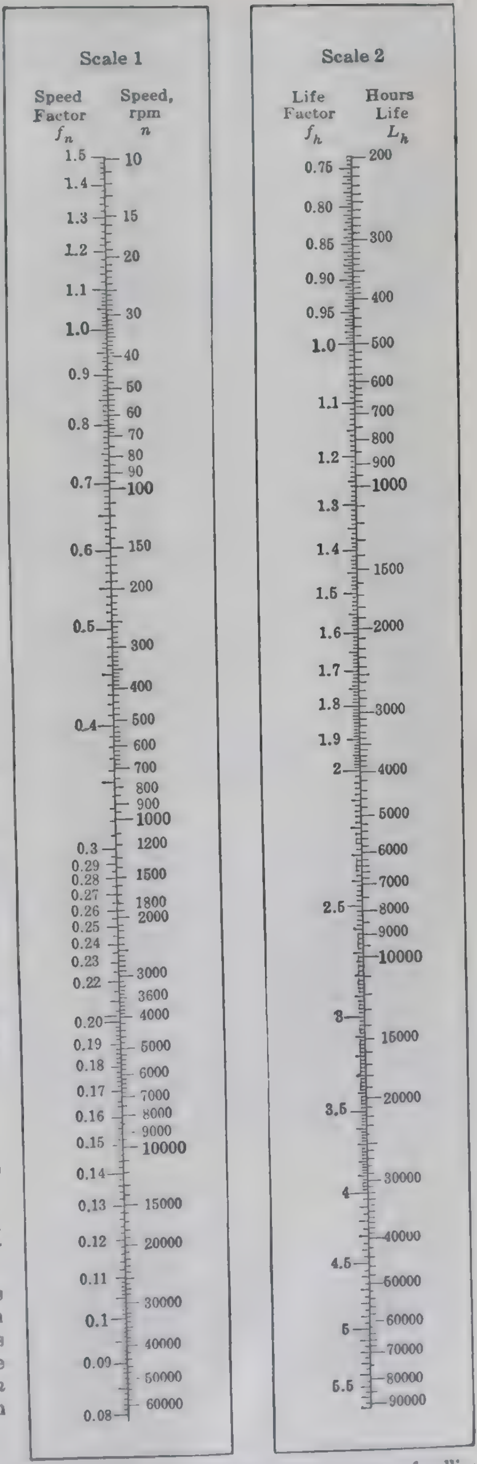

Fig. 4. Scales for life and speed factors of rolling bearings.

where P_1 is the equivalent radial load during N_1 revolutions, P_2 the equivalent radial load during N_2 revolutions $\cdots$, and P_n the equivalent radial load during N_n revolutions. The periods 1, 2, $\cdots$, n are periods within the cycle when the load stays essentially constant.

Table 2. Selection of Bearing Life

Type of Machine	f_h	L_h
Instruments and apparatus which are only infrequently used: demonstration apparatus, devices for operation of sliding doors	1	500
Aircraft engines	1–1.5	500–2,000
Machines for service of short duration or intermittent operation, where service interruptions are of minor importance: hand tools, lifting tackle in machine shops, hand-driven machines in general, farm machinery, assembly cranes, charging machines, foundry cranes, household machines	2–2.5	4,000–8,000
Machines for intermittent service where dependable operation is of great importance: auxiliary machines in power stations, work moving devices in production lines, elevators, general cargo cranes, machine tools less frequently used	2.5–3	8,000–14,000
Machines for 8-hour service which are not always fully utilized: stationary electric motors, gear drives for general purposes	3–3.5	14,000–20,000
Machines for 8-hour service which are fully utilized: machines in general in the mechanical industries, cranes for continuous service, blowers, jackshafts	3.5–4	20,000–30,000
Machines for continuous operation (24-hour service): separators, compressors, pumps, main line shafting, roller beds and conveyor rollers, mine hoists, stationary electric motors, continuously working machines aboard warships	4.5–5	50,000–60,000
Machines for 24-hour service where dependability is of great importance: cellulose and paper machines, public power stations, mine pumps, public pumping stations, machines for continuous service aboard merchant ships	6–7	100,000–200,000

Occasionally the question is asked: How much load can be placed on the bearing while stationary if the bearing is subsequently to rotate without excessive noise or vibration? Although the answer to this question depends on the type of bearing application as well as the type of bearing, a convenient reference point is that load which causes a *permanent* deformation, at the most heavily loaded ball or roller, of 0.0001 of the ball or roller diameter. The load which corresponds to this is about half the dynamic reference capacity for self-aligning ball bearings and approximately equal to the dynamic reference capacity for other bearing types.

For bearings where vibration must be held to a minimum the foregoing limits apply. On other applications which are not so sensitive, either because of low speed of rotation or less accurate operating requirements, several times this load can be applied. For example, aircraft control pulley bearings can support about four times the load given above. Danger of bearing fracture due to overload will occur only after the bearing is loaded to eight times the above limit.

16. FRICTION AND LIMITING SPEEDS

The friction in bearings is compounded from a number of factors, among them the fluid friction of the lubricant, the sliding friction between rolling elements and cage, the sliding friction within the rolling contact areas, and, in roller bearings, the sliding friction between rollers and guide flanges. Slight changes in any of these factors can change the bearing friction considerably, but under ordinary conditions the friction coefficients given in Table 3 can be used and the friction torque found from the equation

$$T = \frac{\mu P d}{2} \tag{5}$$

where μ is the coefficient of friction (Table 3); P is the equivalent radial load, pounds; d is the bearing bore, inches; T is the friction torque, inch-pounds.

Table 3. Coefficients of Bearing Friction

Self-aligning ball bearings	$\mu = 0.0010$
Cylindrical roller bearings with flange-guided short rollers	$\mu = 0.0011$
Thrust ball bearings	$\mu = 0.0013$
Single-row ball bearings	$\mu = 0.0015$
Spherical roller bearings	$\mu = 0.0018$

The speed at which a bearing can safely be run is limited by the amount of heat generated as friction and by the ability of the lubricant to dissipate this heat or to stand the resulting temperature rise without breaking down. In general, grease is a satisfactory lubricant at low speeds. Oil bath lubrication is satisfactory at medium speeds, and circulating oil or special lubrication is necessary at high speeds. While no definite dividing line exists between these different cases, Table 4 gives conservative speed limits for grease and oil bath lubrication. This limit is given in the form of a *dn* factor which is the product of the bearing bore in *millimeters* by the speed in rpm. Since these limits are approximate only, there are conditions which permit grease or oil bath lubrication at somewhat higher speeds and, if oil mist or circulating oil is used, considerably higher speeds can be reached. For example, deep-groove ball bearings and cylindrical roller bearings have been run with circulating oil lubrication at $dn = 1{,}000{,}000$. If the limits given in the table are to be exceeded, however, the lubrication and heat dissipation characteristics should be checked by a competent bearing engineer.

Table 4. Tentative Limiting Speeds for Grease and Oil Bath Lubrication

		Normal Limit for the *dn* Value When Using	
Type of Bearing	Type of Cage	Grease	Oil
Self-aligning ball bearings	**Pressed steel**	200,000	300,000
Single-row deep-groove ball bearings	Pressed steel Pressed bronze ball centered	200,000 200,000	300,000 400,000
Double-row ball bearings	**Pressed steel**	150,000	225,000
Angular contact ball bearings Large angle	Bronze Phenolic composition	200,000	300,000
Angular contact ball bearings Small angle	Machined phenolic composition, ring-centered	200,000 300,000	500,000 700,000
Cylindrical roller bearings	Machined bronze cage, roller-centered	150,000	300,000
Spherical roller bearings	Pressed steel, ring-centered Bronze pressed or machined, ring-centered	100,000 100,000	150,000 200,000
Thrust ball bearings	**Pressed or machined**	150,000	225,000

In most cases the friction which must be considered is not the bearing friction alone but the friction of the total application. If friction type seals are used (see Article 17) the friction of the application will be at least three to five times the friction of the bearing alone. If labyrinth type seals are used, the seal friction is negligible. In general, when friction is a problem the friction of the seals must be considered in the light of seal efficiency and cost and a satisfactory compromise reached.

17. LUBRICATION AND SEALS

Lubrication of bearings may be discussed by dividing the lubrication according to type of lubricant and lubricating device. Although the two common types of seals, *friction* and *labyrinth*, find use with both oil and grease lubrication, there are significant changes in their design for different types of lubricant.

Grease lubrication is used in many small or low-speed jobs where the dissipation of the heat due to bearing and seal friction involves no great difficulty. The grease chosen should be free of acid and corrosive factors and it should be of the proper consistency to give good service under operating conditions (e.g., not so hard that it channels too much and not so soft that it escapes through the seals). The housing and bearing cavity should not be filled more than two-thirds full of grease in order that the bearing friction may not

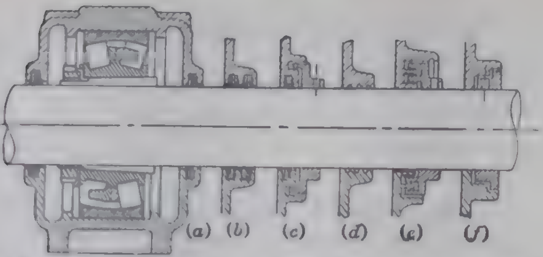

FIG. 5. Seals for grease lubrication (a), (b) friction seals; (c) combination friction and labyrinth seals; (d), (e), and (f) labyrinth seals.

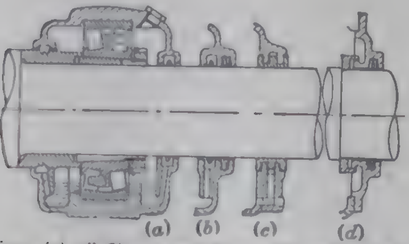

FIG. 6. Seals for oil lubrication: (a) oil flinger and drain; (b) and (d) oil flingers and friction seal; (c) labyrinth ring and drain.

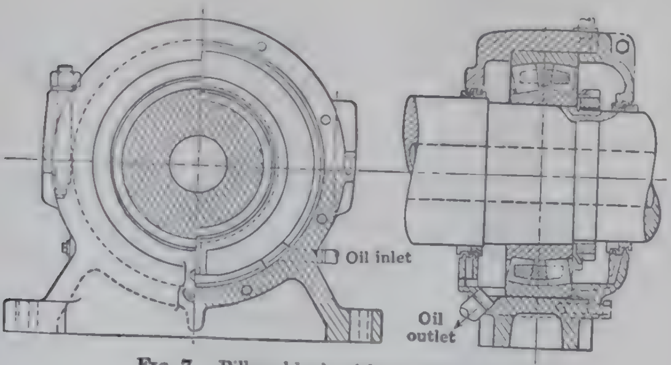

FIG. 7. Pillow block with circulating oil.

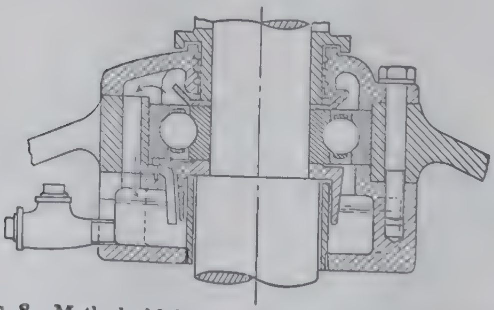

FIG. 8. Method of lubricating a high-speed vertical shaft.

become too high because of excessive churning. If grease is to be injected after a period of operation, care should be taken to see that the new grease reaches a point close to the raceways, and provision should be made for the removal of old grease.

Since grease approaches a solid in consistency, it acts to improve the efficiency of the seals. For that reason, and because of the moderate speed at which most grease-lubricated bearings operate, grease seals are usually fairly simple.

Both friction and labyrinth type seals are in common use with grease lubricated bearings, as is shown in Fig. 5.

Oil lubrication is used when the bearing speed exceeds that for which grease lubrication is satisfactory. It may also be used at lower speeds if more convenient. Oil bath lubrication is used if the speed is low enough so that the oil bath can dissipate the heat of the bearing friction without sufficient temperature rise to cause the oil to carbonize or deteriorate. The level of the oil when stationary should be even with the center of the lowermost ball or roller. A higher oil level causes excessive friction. The viscosity of the oil is determined by the nature of the bearing application. Oil in the bath should have a viscosity of at least 70 Saybolt universal seconds at operating temperature. A somewhat heavier oil is, as a rule, permissible and preferable.

Seals for oil bath lubrication are usually more complicated than for grease lubrication since the oil, being a liquid, flows easily through any simple nonfriction seal. In most cases friction seals tend to lose their efficiency after a short period and allow oil to leak out. Figure 6 shows some labyrinth seals and some combined labyrinth and friction type seals which have been found satisfactory for some oil bath lubricated bearing applications.

For speeds of rotation above that for which oil bath lubrication is permissible, two general methods are in use to insure adequate lubrication. For lightly loaded bearings it may be practical to reduce the bearing friction, and therefore the heat to be dissipated, by blowing an air current which carries a mist of oil to the bearing. This oil is just enough to give the necessary lubrication. By this means the heat of friction is held to a minimum and may be dissipated by ordinary means.

When this method of high-speed lubrication is not satisfactory, a circulating oil system is necessary. Here the heat of friction is much greater since more churning of the lubricant takes place, but this heat is rapidly removed from the bearing by the oil and carried to a cooling tank where the heat is dissipated. Another place where circulating oil may be necessary is in vertical mountings. Figure 7 shows a pillow block and bearing with adequate seals for circulating oil. Figure 8 shows a vertical mounting where an oil supply is brought to the bearing by running up the taper of the rotating shaft and returned to the oil supply by a gravity return.

18. STANDARDS AND TOLERANCES

Standard types of ball and roller bearings are interchangeable parts made to the same dimensions by all manufacturers. The internal design of the bearing may vary slightly with different manufacturers. This interchangeability of standard bearings facilitates their rapid replacement when necessary and is one of the strongest reasons why they should be used in preference to special bearings whenever possible. External dimensions of some standard bearings are given in Tables 5 to 13 and tolerances for these dimensions in Tables 14 and 15.

As can be seen from the tables, standard bearings are manufactured to very precise tolerances. In some cases, however, even greater accuracy is necessary (for example, in machine tool spindles). To meet these needs, bearings of extra- or super-precision tolerances are manufactured in some types and sizes. These bearings may be regarded as semi-standard, in that they are manufactured in fairly large quantities, but they are more costly than standard bearings so that their use is justified only if the rest of the machine is designed for extremely accurate performance. Bearings of extra-precision tolerances are manufactured in deep-groove ball, angular contact ball, ball thrust, and cylindrical roller types. The tolerances are given in Table 16.

Table 16. Tolerances for Extra Precision Radial Bearings

ABEC 5 Tolerances in 0.0001 in.

Inner Ring

Width tolerances are the same as for standard bearings.

In order to prevent creep and subsequent work erosion between the bearing ring and the shaft or housing, the bearing ring which rotates relative to the direction of load should be mounted with a tight fit. Recommendations for shaft and housing fits are given in Tables 17 and 18. The numerical amounts and limits of these fits are given in Tables 19 and 20.

Table 17. Selection of Shaft Tolerances

SHAFTS FOR RADIAL BEARINGS

Conditions		Examples	Ball Bearings	Shaft Diameter, mm		Tolerance Symbol According to ISA	Remarks
				Cylindrical Roller Bearings	Spherical Roller Bearings		
BEARINGS WITH CYLINDRICAL BORES							
Fixed Inner Ring Load	The inner ring to be easily displaced on the shaft	Wheel on stationary shaft	All diameters			g6	
	The inner ring does not need to be easily displaced on the shaft	Tension pulleys and rope sheaves				h6	
Rotating Inner Ring Load or Indeterminate Load Direction	Light and variable loads	Electrical apparatus, machine tools, pumps, ventilators, industrial trucks	≤18			h5	By light and variable loads are meant those which, as a rule, do not exceed 6 to 7% of the specific capacity C. In very accurate applications j5, k5, and m5 are used instead of j6, k6, and m6 respectively
			18 ... 100	≤40	≤40	j6	
			>100	40 ... 160	40 ... 100	k6	
				160 ... 225	100 ... 225	m6	
	Normal and heavy loads	Applications in general, electrical motors, turbines, pumps, combustion engines, gear transmissions, woodworking machines	≤18			j5	
			18 ... 100	≤40	≤40	k5	
			>100	40 ... 160	40 ... 100	m5

			....	....	>500	r7	
	Very heavy loads and shock loads	Journal boxes for locomotives and other heavy rail vehicles, traction motors	....	60 ... 160	60 ... 100	n6	Bearings with greater clearance than normal must be used
			....	160 ... 225	100 ... 200	p6	
			....	....	200 ... 355	r6	
			....	....	355 ... 500	r7	
Pure thrust load		Applications of all kinds	All diameters			j6	

SHAFTS FOR THRUST BEARINGS

Conditions		Shaft Diameter, mm	Tolerance Symbol According to ISA
Pure Thrust Load		All diameters	j6
Combined load on spherical roller thrust bearings	Fixed load on inner ring	All diameters	j6
	Rotating load on inner ring or indeterminate load direction	≤200	k6
		200 ... 400	m6
		>400	n6

Table 18. Selection of Bearing Housing Tolerances

Housings of Cast Iron or Steel for Radial Bearings *

Conditions			Examples	Tolerance Symbol According to ISA	Remarks †
One-piece Bearing Housing	Rotating Outer Ring Load	Heavy loads on bearings in thin-walled housings	Supporting wheels in cranes, wheel hubs with roller bearings, crank bearings	P7	The outer ring is not displaceable axially
		Normal and heavy loads	Wheel hubs with roller bearings, crank bearings	N7	
		Light and variable loads	Conveyor rollers, rope sheaves, tension pulleys	M7	
	Indeterminate Load Direction	Heavy shock loads	Electrical traction motors		
		Heavy and normal loads, axial displacement of outer ring not required	Electrical motors, pumps, crankshaft main bearings	K7	The outer ring is, as a rule, not displaceable axially
Split or One-piece Bearing Housing		Normal and light loads, axial displacement of the outer ring desirable	Electrical motors, pumps, crankshaft main bearings	J7	The outer ring is, as a rule, displaceable axially
	Fixed Outer Ring Load	Shock loads, temporary complete unloading	Journal boxes for rail vehicles		
		All loads	Bearing applications in general, journal boxes for rail vehicles	H7	The outer ring is easily displaced axially
		Normal and light loads, loads under simple operating conditions	Line shaftings	H8	
		Heat supplied through the shaft	Dryer cylinders	G7	
One-piece Bearing Housing	Applications Requiring Particular Accuracy	Very accurate running and small deflections under variable loads	Roller bearings for main spindles in machine tools $D>250$ mm $250 \geqq D > 125$ mm $D \leqq 125$ mm	P6 N6 M6	The outer ring is not displaceable axially
		Very accurate running under light loads and indeterminate load direction	Ball bearings on the working side of grinding spindles, held bearings in high-speed centrifugal compressors	K6	The outer ring, as a rule, is not displaceable axially
		Very accurate running, axial displacement of outer ring desirable	Ball bearings at the driven end in grinding spindles, floating bearings in high-speed centrifugal compressors	J6	The outer ring is displaceable axially

---

* For housings of light metal, tolerances are generally selected which give a slightly tighter fit than those given in the table.

† The notes regarding axial displaceability of the outer ring serve as a guide for judgment of the suitability of the fit, when self-contained bearings are used as floating bearings.

Housings for Thrust Bearings

Conditions		Tolerance Symbol According to ISA	Remarks
Pure thrust load	Thrust ball bearings	H8	In less accurate applications, the housing ring or spherical washer, respectively, is mounted with radial play
	Spherical roller thrust bearing, companion bearing to carry radial load	....	The outer ring is mounted with radial play
Combined load on spherical roller thrust bearings	Fixed load on outer ring	J7	
	Rotating load on outer ring or indeterminate load direction	K7	In general
		M7	In case of comparatively heavy radial loads

19. MOUNTING AND MAINTENANCE

The bearing should be mounted so that the ring which rotates relative to the direction of load has a tight fit on the shaft or in the housing, as the case may be. In the majority of applications a tight fit on the shaft is required. The bearing may be pressed on the shaft by the use of an arbor press, tapped on the shaft by a mounting tube and hammer, shrunk on the shaft after heating, or forced on with mounting nuts. When the bearing is tight on the shaft, it is usually a slide or push fit in the housing and may be pushed in without any trouble.

If the bearing is tight in the housing, the bearing may be mounted by pressing the bearing in the housing. In this case the mounting on the shaft is usually a push fit which can be made without difficulty.

Bearings can usually be removed with the help of bearing pullers and presses. For heavy fits it may be necessary to design into the bearing mounting special methods for removing the bearing. They may consist of removal nuts, hydraulic pressure chambers, etc. A new method which allows an oil film to be pressed between the bearing ring and the shaft or housing breaks the fit and allows the bearing to be pulled off by a comparatively small force.

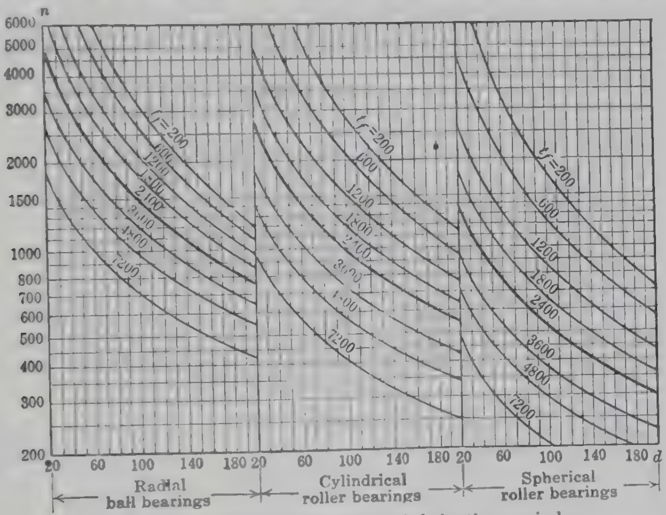

FIG. 9. Recommended grease relubrication periods.

New bearings do not in general need cleaning before using. The best policy is to keep the bearing wrapped until ready to mount. Then remove the bearing from the wrapping, check dimensions and mount, taking care to see that the surroundings are as clean as possible so that no dirt gets in the bearing. Then lubricant should be added and the bearing covers closed so that the bearing is exposed to contamination for as short a time as possible.

When bearings must be removed for cleaning because of caked grease, the bearing should if possible be removed from shaft and housing and soaked in clean cold petroleum solvent or kerosene. If this soaking fails to remove the caked material, soak again in a hot light oil, agitating the bearing container from time to time, and then clean out any remaining material with a hand brush. After cleaning, spin in light oil and relubricate immediately to protect the metal surface. Do not use air to clean bearings. Do not spin bearings until clean and relubricated.

If the bearing cannot be removed easily from the machine, it may be cleaned by flushing hot oil through the bearing. After cleaning, this oil should be completely removed from the bearing and new lubricant inserted.

For a more extensive discussion of bearing mounting and maintenance, consult *Anti-Friction Bearing Maintenance*, compiled by the Anti-Friction Bearing Manufacturers' Association, Inc., 60 East 42nd St., New York 17, N. Y.

If the bearing has oil lubrication, the oil needs replacing only if leakage occurs or if the oil is carbonized by heat. Grease lubrication should be replaced at intervals, depending on the speed and bearing size and type. Suggested grease relubrication periods are given in Fig. 9.

STRAIGHT, NEEDLE, AND TAPERED ROLLER BEARINGS

By E. Stanley Ault

Roller bearings use rollers which are straight or cylindrical, tapered or conical, barrel shaped or convex, hour-glass shaped or concave. The straight roller is suitable for only radial loads, although the raceways may be constructed so that the rollers bear on shoulders at one or both ends to take locating thrusts (Fig. 2, p. 12-67). The rollers may be solid cylinders or hollow cylinders, constructed from strip helically wound. Rollers long in proportion to their diameter are called needle bearings. The tapered roller can sustain both radial and axial loads, and the bearing can be adjusted upon assembly. The convex roller is used in the so-called spherical bearing where it provides some axial load capacity with radial load capacity. So used it is self-aligning. Further discussion and tables on the spherical bearing are found on pp. 12-67 and 12-83. The concave roller is also self-aligning.

20. STRAIGHT ROLLER BEARINGS

WOUND ROLLERS. One form of straight roller bearing made by the Hyatt Bearings Division, General Motors Corporation, uses a hollow roller helically wound from alloy steel strip, heat treated and ground to size (Figs. 10 and 11). Rollers wound right and left hand are assembled alternately in the bearing and held in proper alignment by a cage retainer. Bearings are made with both solid inner and outer races, with solid outer race and no inner race, and with a split outer race and no inner race for use directly on the surface of commercial shafting. Tables 21 and 22 give dimensions and load rating based upon an operating temperature of not more than 350 F; operation at temperatures above 500 F is not recommended. For load ratings required for an average life expectancy other than 5000 hr multiply by factor from Table 23.

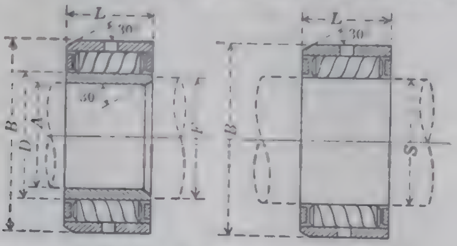

FIG. 10. Wound roller type roller bearing with solid outer race.

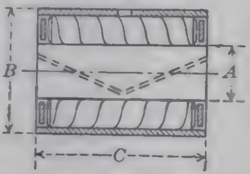

FIG. 11. Wound roller type roller bearing with split outer race.

Temperature Factor (*c*). For temperatures above 350 F the bearing load should be multiplied by one of the following factors to obtain the required rated load:

Maximum temperature, °F	350	400	450	500
Temperature factor, *c*	1.00	1.15	1.37	1.67

Service Factor (*d*). For certain classes of service, depending upon load fluctuations, shock, overload, etc., the bearing loads should be multiplied by one of the following service factors (*d*):

(*Table 21*) Agricultural equipment, trailer trucks, 0.67–1.0; hand-operated hoists, 0.80–1.0; power-house cranes, 0.80; centrifugal extractors, electric motors, industrial locomotive journals and transmissions, 1.0–1.33; mining machinery, except mine cars, 1.33; air compressors, hot saws, sprayers, and dusters, 1.33–2.0; dairy machinery, 1.0–2.0; house-lighting units, 2.0; tractor crawler tracks, 5.0.

(*Continued on p. 12-98*)

Table 21. Dimensions and Load Capacities of Roller Bearings with Wound Rollers with Solid Outer and Inner Races and without Inner Race (See Fig. 10)

(Hyatt Bearings Division, General Motors Corporation, Harrison, N. J.)

Table 21. Dimensions and Load Capacities of Roller Bearings with Wound Rollers with Solid Outer and Inner Races and without Inner Race (See Fig. 10)—*Continued*

(Hyatt Bearings Division, General Motors Corporation, Harrison, N. J.)

Inner Race Inside Diam., A		Roller Assembly Inside Diam., D, or Shaft Diam., S	Outer Race Outside Diam., B	Min. Diam. of Shaft Shoulder, F	Bearing Width, L	Roller Diam.	Outer Race Hole Diam.	Load Rating in Pounds, 5000 hr Ave. Life Expectancy The load rating of the bearing selected must be at least equal to $L \times a \times b \times c \times d$, where L = imposed bearing load, a = shaft hardness factor, b = stationary shaft factor, c = temperature factor, and d = service factor. Values of these factors are given. Shaft hardness Rockwell C - 54.

Table 23. Factors for Various Desired Life Expectancies

(Hyatt Bearings Division, General Motors Corporation)

Desired Ave. Life, hr	Life Factor	Desired Ave. Life, hr	Life Factor	Desired Ave. Life, hr	Life Factor
1500	0.548	5000	1.000	15000	1.732
2000	0.633	6000	1.096	20000	2.000
2500	0.707	7000	1.183	25000	2.236
3000	0.775	8000	1.265	30000	2.450
4000	0.894	9000	1.342	40000	2.828
4500	0.949	10000	1.414	50000	3.162

(*Table 22*) Pintle bearings, 0.25; hand trucks, 0.4–0.67; industrial car caster wheels, 0.5–0.67; hand-operated cranes and hoists, 0.80–1.0; steel mill cars, charging cars, ingot cars, 0.67; agricultural equipment, gravity conveyors, industrial cars, contractors' cars, 0.67–1.0; hand-operated hoists, 0.80–1.0; mining machinery, except cars, 1.33; belt conveyor idlers, rotating shafts, 2.0–2.8; soaking pit covers, 3.0; belt conveyor idlers, stationary shafts, 3.0–4.0.

For unusual conditions the manufacturer should be consulted for the proper load rating.

Stationary Shaft Factor (*b*). Required rated load for stationary shaft in bearings with raceways is obtained by multiplying bearing load by 1.33. For bearings without inner raceway, use factors from table.

Lubrication of wound roller bearings depends upon the speed and temperature. The Hyatt Bearings Division gives a chart showing the range of speed for various shaft diameters by which it may be classified as operating at low, medium, or high speed. From this chart the following figures are taken:

Shaft diameter, in.	1	1 1/2	2	2 1/2	3	4	5
Low speed, max rpm	550	400	300	230	200	150	120
Medium speed, max rpm	1400	1140	940	800	670	510	400

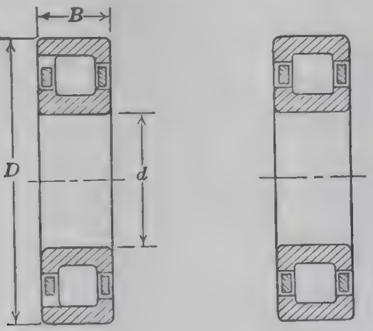
Table 24 gives the viscosities recommended for these bearings by the manufacturer. Ordinarily the lightest oil that will stay in the housing should be used. When leakage prevents the use of oil, grease may be used. The grease should be a well-blended mixture of highly refined oils and carefully prepared soap, without filler. Calcium or lime soap greases may be used at temperatures below 150 F and speeds below 300 rpm. Soda-lime or mixed base greases are satisfactory up to 250 F and at higher speeds.

Table 24. Viscosity of Oils for Wound Roller Bearings

(Hyatt Bearings Division, General Motors Corporation)

Atmospheric Temperature, °F	Viscosity, SUS		
	High Speed	Medium Speed	Low Speed
− 20 to 32	100–160 @ 100 F	100–250 @ 100 F	160–325 @ 100 F
32 to 150	130–225 @ 130 F	60– 70 @ 210 F	70– 80 @ 210 F
150 to 250	70– 80 @ 210 F	70– 80 @ 210 F	70– 80 @ 210 F
250 to 500	80–105 @ 210 F	80–125 @ 210 F	105–150 @ 210 F

SOLID ROLLER BEARINGS. Solid roller bearings comprise a series of solid cylindrical rollers confined between inner and outer raceways, and held in position relative to each other by cages or spacers. The inner raceway frequently is grooved to prevent endwise movement of the rollers (Fig. 2*a*). In some cases the inner raceway may be the shaft or spindle itself. The outer raceway may be a plain ring. The rollers then are free to move endwise across the face of the raceway, thus permitting endwise movement of the shaft, or the outer raceway may have a single lip or two lips (Fig. 2*b* and *c*), forming a groove in the raceway, thus locating the shaft endwise. The outer raceway may be turned to the surface of a sphere and enclosed in a ring with a spherical interior surface, making a self-aligning bearing.



(*a*) (*b*)

FIG. 12. Solid roller bearings: (*a*) one-lip, (*b*) two-lip type.

Typical forms of solid cylindrical roller bearings are shown in Fig. 2 (*a*, *b*, and *c*) and in Fig. 12. Dimensions and ratings of typical metric bearings are listed in Table 10. Inch-series bearings are listed in Table 25. While the ratings in Table 10 are for one million revolutions with the inner ring rotating relative to the load direction, those in Table 25 are based on an average life expectancy of 10,000 hr. To get the required rating for other desired life expectancies multiply the bearing load by the proper life factor listed at the bottom of the table.

Table 25. Dimensions and Load Capacities of Solid Cylindrical Roller Bearings

(Norma-Hoffman Bearings Corporation, Stamford, Conn.)

Bore	Outside	Width	Rollers		Load Rating, lb								
					Based upon rotating shaft for 10,000 hr average life expectancy. For outer race rotation multiply speed by following factor before selecting rating: heavy series, 1.7; medium, 1.6; light 1.5; all others, 1.2.

21. NEEDLE BEARINGS

Needle bearings are bearings using solid cylindrical rollers whose length to diameter ratio is relatively large, recommended to be between 6 to 1 and 10 to 1. The rollers are generally assembled without a cage, thus allowing the use of a large number of rollers. These bearings are suitable for only radial load and are particularly useful where diametral space is limited. The long rollers are kept in alignment by the outer race. Axial restraint is provided by flanges on the race. The needle bearing is well adapted to low-speed or oscillating operation but can be designed for successful operation at high speeds. Rollers may operate directly on shaft and bearing seat or be contained in a manufactured bearing assembly. Load capacity is greatly affected by rigidity of raceway and supports.

LOOSE-ROLLER BEARINGS. The capacity of the rollers is greater than that of the raceways. The Torrington Company recommends a raceway hardness of Rockwell C 60 minimum. Hardness less than this results in marked reduction of carrying capacity.

A roller diameter equal to 10% of pitch diameter gives a well-proportioned bearing; higher-speed rotating shafts use a higher ratio and lower-speed oscillating shafts a lower ratio (to $2\frac{1}{2}$%). Load for shaft rotation and dimensional relationships recommended are:

$$R = \frac{32{,}000 D_p L}{\sqrt[3]{S}} \qquad (1) \qquad \text{or} \qquad R = 2200\, NLd \text{ at 100 rpm} \qquad (2)$$

$$D_p = Kd + \frac{N(cc)}{\pi} \qquad (3) \qquad D = D_p - d - (dc) \qquad (4)$$

$$B = D_p + d \qquad (5) \qquad N = \frac{\pi D_p}{d + (cc)} \qquad (6)$$

where R = rated load, pounds; S = speed of bearing, rpm; L = effective roller length, inches; D_p = pitch diameter, inches; D = shaft diameter, inches; B = housing bore diameter, inches; N = number of rollers; (cc) = circumferential clearance per roller, inches; (dc) = diametral clearance, inches; $K = 1 \div \sin 180°/N$. A convenient table of values of K, $N(cc)/\pi$, and their combination is given in the Torrington Company Catalog. Selected values of K are reproduced in Table 26.

The capacity for oscillating shafts is taken the same as for rotation at 100 rpm.

Table 26. Values of $K = 1 \div \sin 180°/N$

3 1/2	4	3/4		55	.2118	12550	5025	4000	3775	2335	1850				

Circumferential clearance (*cc*), except for special circumstances, is 0.0001 in. per roller plus tolerances. For severe operating conditions this clearance would be reduced.

Diametral clearance (*dc*) for rotating shaft should be 0.0005 in., minimum, seldom greater than 0.002 in. with maximum tolerances.

Raceway tolerances are plus zero, minus 0.0005 in. for inner or shaft and minus zero, plus 0.0005 in. for outer raceway bore.

Roller tolerances are minus 0.0002 to 0.0004 in. for diameter and minus 0.020 in. for length. Minimum roller end play against end retainers is 0.010 in. For moderate service, retainers may be flat, split rings, although heavy retainers increase capacity.

Table 27 gives stock sizes of needle rollers with rounded ends. Where load is greater on one end of bearing, or greater length is required, two or more rows of rollers may be used with hardened, ground spacers between the roll ends.

UNIT-ASSEMBLY BEARINGS. The Torrington Company manufactures unit assemblies with hardened, pressed-steel housing for press fit in a bored housing, assemblies with outer race and heavy end guards, and inner races for use with soft shafts.

Table 28 gives sizes and rated capacity at 100 rpm of shaft based upon 3000 hours average life expectancy when used on a shaft hardened to Rockwell C 52. Capacity for oscillating shafts is taken same as that at 500 rpm. For outer race rotation use 85% of listed load values.

22. TAPERED ROLLER BEARINGS

The tapered roller bearing is constructed upon the principle of rolling cones, the elements of rollers and raceways converging to a common intersection on the axis of the bearing (Fig. 13). True rolling motion is obtained along the cone elements, and the bearing will sustain radial or thrust loads, or any combination of them. The essential parts are an inner raceway or cone, an outer raceway or cup, tapered rollers, and a cage or roller retainer (Fig. 14). The end thrust on the rollers is balanced by a shoulder on the cone, and the retainer acts merely as a spacer, and sustains no load.

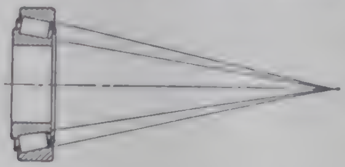

Fig. 13. Basic principle of tapered roller bearing.

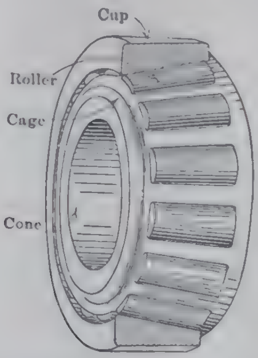

Fig. 14. Standard single-row tapered roller bearing.

BEARING SELECTION. Dimensions and rated capacity of selected bearings of the various types are listed in Tables 29 to 33. Data for other sizes and types may be obtained from the manufacturers.

The bearings are rated for both pure radial load, BRR, and for pure thrust load, BTR, for 3000 hours B-10 (or minimum) life expectancy at 500 rpm of shaft rotation. Average life is about five times B-10 life. The required radial rating at 500 rpm of the bearing is $R \times LF \times AF \times SF$, where R is the calculated or equivalent radial load, LF is the life factor from Table 34, AF is the application factor, and SF is the speed factor, obtainable from Table 35.

For stationary shaft, radial load on bearing must be multiplied by 1.7, thrust load by 1.00.

Application factor is frequently unity, values greater than unity being 1.33 for farm tractor wheels, feed grinders, hammer mills, paper mill machinery, commercial stokers; 1.5 for printing machinery, rubber machinery, dredge pumps; 1.75 for automotive wheels and differentials; 2.00 for farm machinery and highway trailers.

Where hours of life are not specified but are dependent upon type of equipment, the following values may be used for life factor: 1.00 for automotive, meat slicers, farm machinery, and tractor transmissions, household appliances, lawn mowers, portable tools, spray and household pumps, road machinery, household stokers, highway trailers; 1.25 for steel mill machinery; 1.5 for amusement devices, belt drives, clay-working machinery, farm and industrial engines, tractor wheels, gear reduction units, feed grinder and hammer mills, I-beam trolleys, pulverizing and screening equipment, railway section cars, and commercial stokers; 2.0 for dough mixers, elevators, industrial and oil-field engines, glass-making and grain-milling machinery, cranes and hoists, ice-making, laundry, and leather-working machinery, locomotives, machine tools, cement plant, and printing equipment, deep-well, fire, and dredge pumps, railway car drives, rubber, wood-working, textile machinery; 3.0 for large stationary compressors, paper mill pumps, and machinery.

For thrust load the bearing is selected from the thrust rating in the same manner.

A radial load on a tapered roller bearing induces a thrust equal to $0.47/K$, where

$$K = \frac{\text{Radial load rating of bearing}}{\text{Thrust load rating of bearing}} = \frac{\text{BRR}}{\text{BTR}}$$

Values of K for a bearing may be computed from the given ratings; usual values of K are for standard bearings about 1.5; for steep-angle bearings about 0.75.

For a bearing simultaneously subjected to a radial load R and a thrust load T, the equivalent radial load,

$$ER = 0.53R + KT \text{ for rotating shaft}$$

and

$$ER = 1.23R + KT \text{ for stationary shaft}$$

When the applied radial load is greater than the equivalent radial load, the radial load is used.

When a shaft is supported on two opposed bearings A and B so that A carries practically the whole radial load, the equivalent radial load on B is then

$$ER_B = 0.53R_B + 0.47R_A\left(\frac{K_B}{K_A}\right) \text{ for rotating shaft}$$

$$= 1.23R_B + 0.47R_A\left(\frac{K_B}{K_A}\right) \text{ for stationary shaft}$$

If bearing B carries a thrust load T_B also,

$$ER_B = 0.53R_B + K_B\left(T_B + \frac{0.47R_A}{K_A}\right) \text{ for rotating shaft}$$

$$= 1.23R_B + K_B\left(T_B + \frac{0.47R_A}{K_A}\right) \text{ for stationary shaft}$$

THE STANDARD BEARING is made in three basic series, heavy, medium, and light. They are established by maintaining fundamental relations between the various components of the bearing. The standard or heavy series has wide races and long rollers; the light series has narrow races and short rollers; the medium series is an approximate mean between the other two. (See Table 29.) The standard type of bearing is a general service bearing. It is widely used in automotive vehicles, machinery, farm implements, mining machinery, etc.

THE STEEP ANGLE BEARING (Fig. 15) is used in power take-offs, worms and bevel gear shafts, etc., where the thrust load predominates, although there is an appreciable radial load. It is similar to the standard bearing except that the angles of both the raceway and rollers are quite steep. (See Table 30.)

FLANGED CUP BEARINGS (Fig. 16) are used where extreme precision is required as on machine tool spindles. The bearing housing is bored straight through, and a seat faced at right angles to the bore. This face provides a backing for the flange of the cup. This bearing also is used where there is insufficient space for conventional bearing-mounting methods, and where the housing is of manganese steel or other material difficult to machine. Table 31 gives dimensions and capacities.

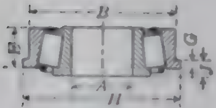

Fig. 16. Single-row flanged-cup tapered roller bearings.

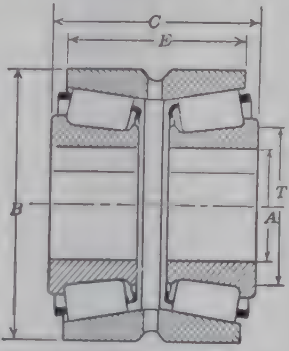

Fig. 17. Two-row double-cup single-cone tapered roller bearing.

MULTIPLE-ROW BEARINGS provide maximum load-carrying capacity in small space, resist thrust loads from both directions, and maintain a precise and rigid mounting or a floating assembly as desired. They are made in several types as follows:

Two-row Double-cup Single-cone Bearings (Fig. 17). Three assemblies are possible. (1) A spacer is introduced between the cones to establish the set-up or running clearances at the time the bearing is assembled. (2) The cones are butted together, thus establishing the proper running clearance. (3) No cone spacer is used, and the proper clearance is obtained by some form of adjusting device. Types 1 and 2 usually are preferred if quick removal and replacement of bearings are necessary, or if operating conditions do not necessitate take-up after a long period of service. With this type of bearing, shaft expansion is provided for by locking the cone in position and permitting the cup to float in the housing. The opposite end of the shaft usually is fixed in position, and movement is confined to one end. Both conventional and steep-angle assemblies are possible with this bearing. (See Table 32.)

Two-row double-cone single-cup bearings (Fig. 18) are used when the capacity of a two-row bearing is required, with a simpler mounting than two standard single-row bearings. They also are used on the fixed end of a shaft when allowance must be made for shaft expansion. The bearing used on the opposite end then usually is a floating double-cup unit. (See Table 33.)

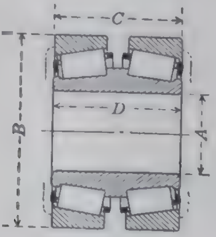

Fig. 18. Two-row double-cone single-cup tapered roller bearings.

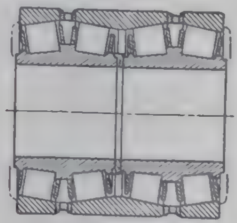

Fig. 19. Four-row tapered roller bearing.

Four-row bearings (Fig. 19) are used where maximum capacity is required in a limited space, as in rolling mills, cement plants, rubber mills, and other units which develop extreme pressures. It comprises four sets of rollers. The arrangement is similar to two double-cone bearings set side by side with a double cup carrying the load from the two inner sets of rollers and a single cup carrying the load imposed on the two outer sets of rollers. Spacer rings are recommended in all applications. Manufacturers should be consulted regarding application of this type of bearing.

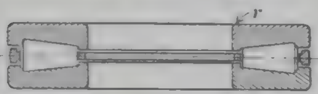

FIG. 20. Tapered roller thrust bearing.

Thrust bearings to withstand thrust loads only without radial loads are shown in Fig. 20.

METHODS OF MOUNTING TAPERED ROLLER BEARINGS. Figure 21 shows various methods of mounting tapered roller bearings. Design 1 is for those cases where the maximum possible shaft extension diameter is desired. In design 2 it is possible to use a smaller size nut than in design 1, and yet have the necessary cone backing. Design 3 uses a single lock nut and tongued washer to clamp another member through the cones. A small spacer is necessary before the front face of the cone to prevent interference by the washer with the bearing cage. The diameter of the spacer must be such as to provide cage clearance. In design 4 the nut should provide sufficient backing to clamp the assembly solidly. Design 5 is a typical automotive application. A hardened tongued washer is used between the inner nut and cone face. The length of thread and keyway must be increased by the thickness of the hardened washer. Table 36 gives dimensions of lock nuts and tongued washers. For data concerning the theory of tapered roller bearings and their application to various services consult the Timken *Engineering Journal* published by the Timken Roller Bearing Company, Canton, Ohio.

LUBRICATION. Table 37 gives the specifications of lubricants recommended for tapered roller bearings by the Timken Roller Bearing Company. In general, bearings less than 6 in. outside diameter, operating at speeds of less than 1000 rpm, without unusual conditions may be lubricated with a lime or soda base grease of medium consistency. With moisture present, only a lime base should be used. For speeds above 1000 rpm, oil is more satisfactory, but grease may be used on the smaller bearings. Grease is recommended for bearings over 6 in. outside diameter only up to 500 rpm. High-speed bearings are best lubricated with light oil and a drop feed or wick system with provision to drain excess oil to avoid heat due to churning. The drain should be located so that the lowest point of the bearing is not immersed more than $\frac{1}{8}$ in. A circulating oil system is recommended for conditions of extreme heat. For unusual conditions, advice as to lubrication should be obtained from the makers of the bearings.

For general machinery applications, grease should be compounded from a high-grade soap and a refined mineral oil, free from acid, alkali, and fillers that would tend to score the bearing. A bright copper or steel plate, submerged in the grease for 24 hr, should show no discoloration. Ash and moisture should not exceed 2%. Oil from which the grease is compounded should have a minimum flash point of 340 F, a minimum fire point of 380 F, and a Saybolt universal viscosity of 200 sec at 100 F. For heavy-duty applications the greases should follow the same general specifications. The oil from which they are compounded should conform to the following: flash point, min, 375 F; fire point, min, 425 F; min Saybolt universal viscosity, 75 sec at 210 F; pour test, max 40 F.

MACHINE HYDRAULICS

It is the purpose of this chapter to describe the various hydraulic principles and elements used in the hydraulic actuation of machinery. The detailed design of the various elements does not come within the scope of this discussion, but references are given to books and articles that will serve to amplify this text.

The basic principles on which our modern hydraulic machines are founded were discovered by early physicists, Archimedes, Galileo, Torricelli, Pascal, and others. From early practical use of hydraulics the art developed with the invention of better pumps, accumulators, control valves, and suitable hydraulic fluids. Until the end of the nineteenth and the early years of the twentieth century hydraulics was used chiefly for pressing, hoisting, and elevating. The use of hydraulics in machine tools for feeds, clamps, drives, and controls is a relatively recent development.

1. FLUID FLOW AS APPLIED TO MACHINE HYDRAULICS

The flow of a hydraulic fluid in a pipe line or through a valve is a function of pressure differential, temperature, viscosity, surface condition, length of the flow path, and Reynolds' number. Viscosity is a function of temperature and inherent characteristics of the fluid. It will be discussed separately.

REYNOLDS' NUMBER is the nondimensional product of pipe or orifice diameter, fluid velocity, and the reciprocal of kinematic viscosity:

$$N_R = DV\frac{1}{\nu} \tag{1}$$

where N_R is Reynolds' number; D is diameter of pipe, feet or inches; V is average fluid velocity, feet or inches per second; and ν is kinematic viscosity, feet^2 per second or inches^2 per second. In viscosity tables ν is usually given in stokes or centistokes in the cgs system. The conversion is

$$\begin{aligned} \nu \text{ in ft}^2/\text{sec} &= \nu \text{ in stokes} \times 0.001077 \\ 1 \text{ stoke} &= 100 \text{ centistokes} \\ &= 1 \text{ cm}^2/\text{sec} = 0.001077 \text{ ft}^2/\text{sec} \end{aligned} \tag{2}$$

When the Reynolds' number of a given flow condition is less than 2000 the flow is viscous or streamline and the "friction factor" in a smooth pipe is

$$f = \frac{64}{N_R} \tag{3}$$

This is known as the Hagen-Poiseuille law. Above 4000 the friction factor follows no simple equation. Values of f for three types of pipe are given in the Stanton diagram, Fig. 1. Those values are for flow in a substantially straight pipe of uniform cross section and surface condition.

In the range between 2000 and 4000 the type of flow is indeterminate. If the flow starts at a Reynolds' number of less than 2000 it will remain viscous until it reaches 4000. Likewise if the flow starts at a Reynolds' number in excess of 4000 the flow will remain turbulent as the Reynolds' number decreases until approximately 2000 has been reached. The point of change from turbulent to viscous or vice versa is not exact and may not be the same for two successive runs in the same systems.

PRESSURE LOSS. In calculating the pressure loss in a pipe line the friction factor f from Fig. 1 is used in Fanning's equation:

$$\frac{P_1 - P_2}{L} = \frac{f\rho V^2}{2D} \tag{4}$$

$$= \frac{f\omega V^2}{2gD} \tag{5}$$

where L = length of pipe, feet; ρ = absolute density, slugs per foot^3; V = average velocity, feet per second; D = internal diameter of pipe, feet; P_1 and P_2 = pressure or

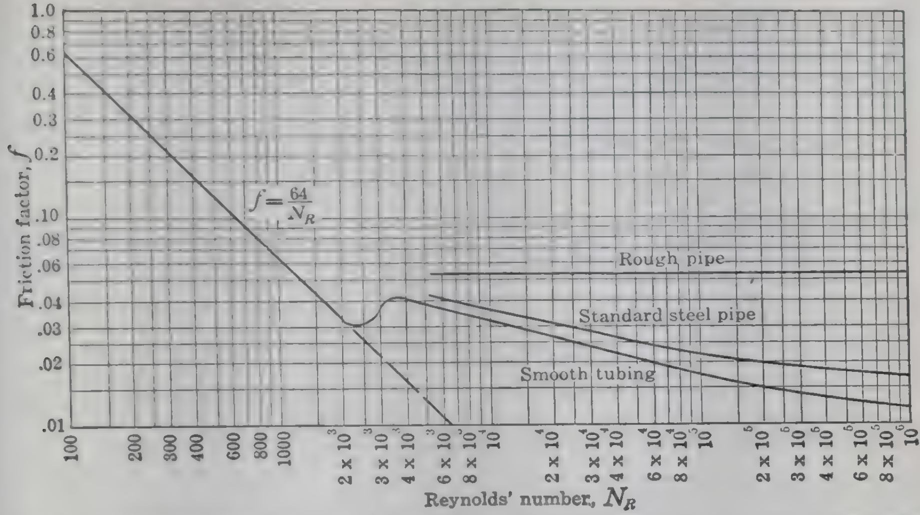

FIG. 1. Friction factor as a function of Reynolds' number for straight pipe of uniform cross section and surface condition. (Reproduced by permission from *Heat Exchanger Tube Manual*, Scovill Manufacturing Co.)

head, pounds per square foot; ω = weight of fluid, pounds per foot^3; g = gravity constant, feet per second^2; and f = friction factor.

Equation 4 can be simplified for practical use by substituting for f its equivalent in eq. 3. This gives for **viscous flow:**

$$P_1 - P_2 = L \frac{64}{N_R} \frac{\rho V^2}{2D} \tag{6}$$

which, when DV/ν is substituted for N_R, gives

$$P_1 - P_2 = \frac{L 32 \rho V \nu}{D^2} \tag{7}$$

$$= \frac{L 32 \omega V \nu}{g D^2} \tag{8}$$

For **turbulent flow** the Blasius approximation for smooth pipes can be used, where

$$f = \frac{0.316}{\sqrt[4]{N_R}} \tag{9}$$

Giving:

$$P_1 - P_2 = \frac{L 0.316 \rho V^2}{2D \sqrt[4]{N_R}} \tag{10}$$

$$= \frac{0.158 L \rho V^{7/4} \nu^{1/4}}{D^{5/4}} \tag{11}$$

VISCOSITY is the measure of internal friction in the fluid. A high viscosity number indicates a fluid that flows with more difficulty than one with a low viscosity number. *Absolute viscosity* is measured in poises in the cgs system of units. A poise has the dimension of M/LT or grams mass per centimeter × seconds. In the engineering system of units this would be slugs per foot-second.

$$1 \text{ poise} = 0.00209 \text{ slug/ft-sec} \tag{12}$$

A more common measure of viscosity is *kinematic viscosity*. This is an arbitrary unit which is the quotient of absolute viscosity divided by absolute density:

$$\frac{\mu \text{ in slugs/ft-sec}}{\rho \text{ in slugs/ft}^3} = \nu \text{ in ft}^2\text{/sec} \tag{13}$$

Its dimension is therefore L^2/T.

Since in the cgs system absolute density and specific gravity are numerically equal it is convenient to change absolute viscosity in poises to kinematic viscosity in stokes before

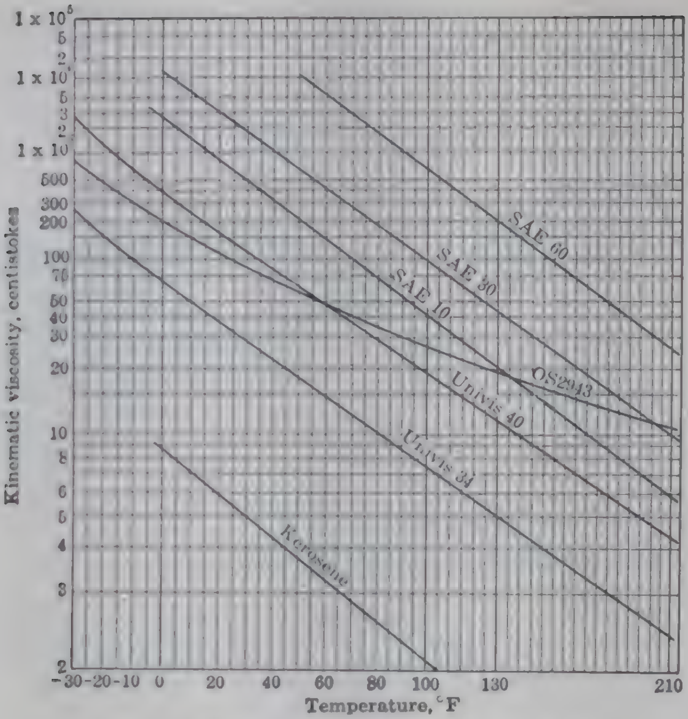

FIG. 2. Kinematic viscosity of typical hydraulic fluids.

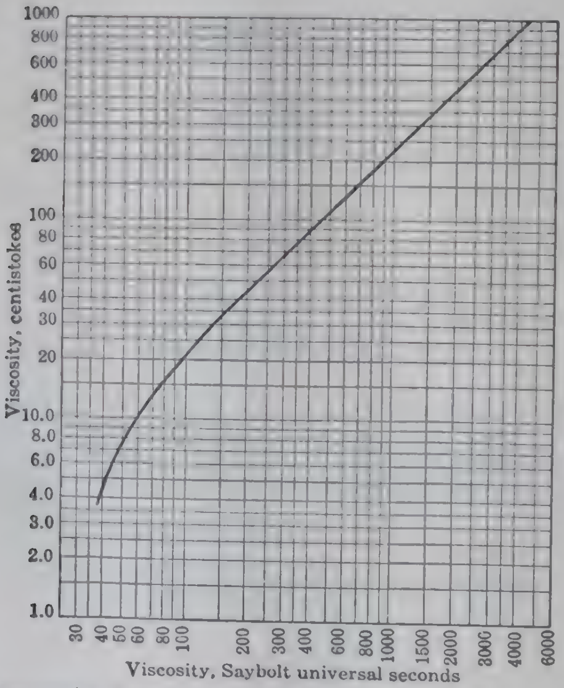

FIG. 3. Chart for converting Saybolt viscosity to kinematic viscosity. (Courtesy of Fischer and Porter Co.)

conversion to the engineering units of slugs, feet, and seconds. Note the conversion factor in eq. 2. Graphs of viscosity versus temperature for various hydraulic oils are shown in Fig. 2. The viscosity of hydraulic fluid is frequently given in units of Saybolt universal seconds at a specific temperature. Viscosity in these units can be converted to kinematic viscosity in centistokes by using the conversion chart in Fig. 3.

ORIFICE CALCULATIONS. The flow of fluid through an orifice is expressed by the relation

$$Q = kA\sqrt{\Delta p} \tag{14}$$

where Q = quantity flowing in unit time, foot^3 per second; k = orifice constant; A = area of orifice, feet^2; and Δp = pressure drop across orifice, pounds per inch^2.

Equation 14 is based on the basic formula for velocity of a fluid:

$$V = \sqrt{2gh} \tag{15}$$

and since

$$Q = AV_1 \tag{16}$$

where V = actual velocity at given point in the fluid and V_1 = average velocity over orifice. Then

$$Q = k_1AV \tag{17}$$

$$= k_1A\sqrt{2gh} \tag{18}$$

where k_1 is a velocity correction constant, g is the gravity constant, and h is head in feet.

In order to make eq. 18 more convenient to use, it is often written in the form of eq. 14 in which the constant k contains the constant k_1 of eq. 18, the factor $2g$, and a factor converting h to Δp in pounds per square inch. Constant k is not nondimensional and Δp is not in fundamental units, so care must be exercised not to use this equation in developing others unless proper regard is paid to its factors. It is, nevertheless, most useful in orifice flow calculations.

Orifices are used for measuring fluid flow by measuring the value Δp on a manometer or a differential pressure gage. A typical installation is diagrammed in Fig. 4, h in the diagram being the measure of h in eq. 18. It must be converted by multiplying by the ratio of the specific gravity of the manometer fluid to the fluid being measured.

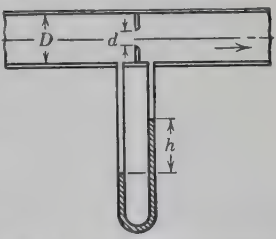

FIG. 4. Flowmeter employing orifice and differential pressure measurement.

Figure 5 illustrates the effect of viscosity on the orifice constant by showing its variation with Reynolds' number. Viscosity influences the orifice constant because of the proximity of the tube or pipe wall.

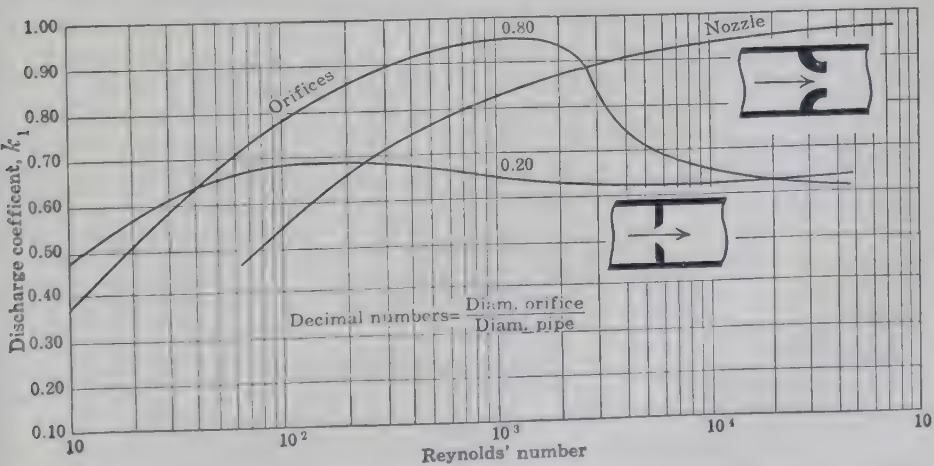

FIG. 5. Discharge coefficients of nozzles and orifices as a function of Reynolds' number. (Courtesy of Fischer and Porter Co.)

COMPRESSIBILITY OF HYDRAULIC FLUIDS. Hydraulic fluids are commonly thought of as incompressible but they actually have relatively low moduli of elasticity.

Mineral oil commonly used in hydraulic circuits has a modulus of elasticity on the order of 200,000 psi; water has a modulus of 300,000 psi. These are bulk moduli.

Because of this compressibility of hydraulic fluids they cannot be depended upon to locate accurately a piston under varying loads or give uniform velocity to a motor under varying torque. Pressure surges and vibration in the fluid are possible because of this compressibility.

2. HYDRAULIC CIRCUITS

CONSTANT-PRESSURE CIRCUIT. The simplest type of hydraulic circuit is the constant-pressure circuit. This is illustrated in Fig. 6. A constant-discharge hydraulic pump delivers oil to a main line to the directional control valve. In this main line is a pressure-regulator valve and a pressure-indicating gage. In the circuit illustrated, the directional control valve is a three-way type and directs the flow of oil to and from the actuator (a piston and cylinder or a hydraulic motor). This simple type of system operating at constant pressure is inefficient. The pump continues to operate at full flow, pressure, and power even though the actuator has reached the end of its stroke or has stalled. The power consumed by the pump is dissipated in the form of heat in the oil; this heat must be taken out of the oil by radiation from the various components in the circuit.

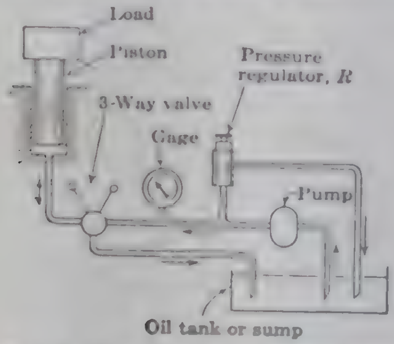

FIG. 6. Constant-pressure hydraulic circuit.

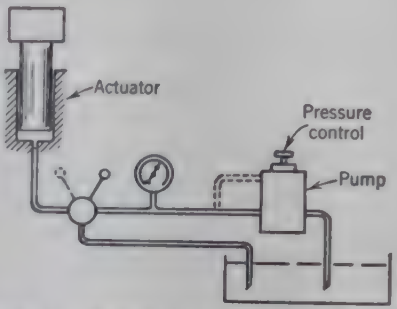

FIG. 7. Variable-discharge hydraulic circuit.

This general type of simple hydraulic system is used in small installations where the power requirements do not exceed a few horsepower. It becomes exceedingly difficult to get rid of the waste heat in larger units and it becomes more economical to use a variable-discharge pump.

VARIABLE-DISCHARGE CIRCUIT. Figure 7 illustrates a circuit utilizing a variable-discharge pressure-controlled pump. This pump has a theoretical pressure-discharge characteristic as shown by the dotted line in Fig. 8. When the discharge pressure is zero the pump adjusts itself to maximum discharge. As the pressure increases there is a small loss in discharge until pressure P is reached. This is the operating pressure for the hydraulic system. As the pressure is increased slightly to P_2, when the load on the actuator increases or stalls, the pump discharge is adjusted automatically to zero. The power required to operate the pump at zero discharge is very low and the oil remains relatively cool. The rest of the circuit is the same as Fig. 6.

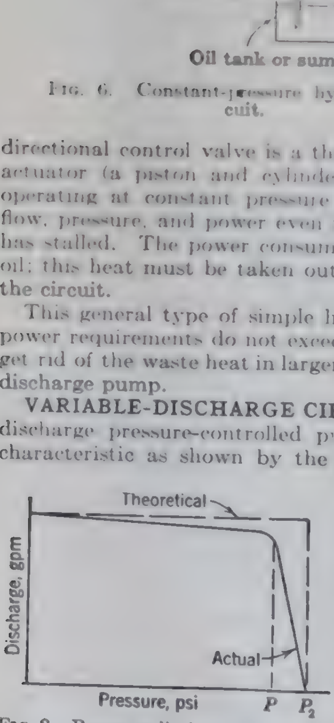

FIG. 8. Pressure-discharge characteristics of pump used in variable-discharge circuit.

ACCUMULATOR CIRCUIT. Figure 9 illustrates a simple accumulator-operated hydraulic circuit. This circuit uses a simple constant discharge pump in connection with an unloading valve. This valve is so designed that when the pressure in the accumulator reaches the desired value the valve shifts and allows the oil to by-pass back to the tank at substantially zero pressure. When the directional control valve is operated to direct oil into the actuator, the oil in the accumulator is consumed; and when the accumulator reaches the end of its stroke, the resultant pressure drop causes the unloading valve to shift, closing its by-pass port and again directing oil from the pump to the accumulator and the main circuit. Since the pump is operating at substantially zero pressure for a large part of the time very little power is consumed and consequently little heat must be dissipated.

This is a more expensive circuit to use since the accumulator and the unloading valve are relatively costly parts. It is, however, a good circuit to use where the hydraulic power is applied over a short period of the entire cycle.

MULTIPLE-PRESSURE CIRCUIT. Figure 10 illustrates a multiple-pressure system in which pressure-regulating valves are placed in series, the discharge from one feeding the next pressure circuit. In this type of circuit each succeeding pressure cannot be made higher than the preceding one. It is obvious that as the last valve pressure is increased it will increase the pressure by a like amount in the preceding circuit unless specially designed valves are used. If the primary regulator is properly designed, the variations in the downstream pressure regulated by the secondary regulator will not affect the upstream pressure until the two are equal. Any increase in the downstream pressure above this point regulates the pressure in the entire circuit.

One or more actuators can be operated from each pressure circuit. The number of circuits that can be operated in this cascade fashion is unlimited.

MANIFOLD CIRCUIT. Figure 11 illustrates a multiple-pressure system in which a regulating valve R_3 regulates a maximum manifold pressure and pressure-reducing valves R_1, R_2, etc., determine the pressure in branch lines from the manifold. This type of circuit must be used when the various pressures must be entirely independent of each other.

Since the fundamental circuit involving the pump, manifold, and regulating valve is identical to that in Fig. 6, the same faults apply to this one. It is inefficient and tends to cause excessive heating of the oil. It is therefore limited to relatively low powers. Here again, a variable-discharge pump can be used to advantage.

The branch lines may consist of one or a number of actuators. It should be noted that where two or more actuators receive their energy from a single source, means must be provided to prevent oil from discharging from one or a number of actuators under pressure to an actuator just operated. Usually a check valve in the branch supply line is sufficient to prevent excessive "wink" in one actuator when another is connected on the line.

3. HYDRAULIC FLUID PUMPS

PISTON PUMPS. The simplest and earliest type of fluid-pressure pump is the single-cylinder, single-acting, hand-operated pump, such as is used on common automotive jacks or as auxiliary pumping equipment on aircraft. This unit is illustrated in Fig. 12. It consists primarily of a cylinder body, containing the inlet and discharge valves, oil-line couplings, and means for mounting the actuating handle. The piston is usually internally sealed and linked to the actuating handle. Pressures up to several thousand psi can be achieved with this type of pump but the volumetric displacement is low since it is not possible for the average man to exert a continuous force of over 50 lb on the actuating handle.

Early high-pressure pumps were limited to bulky "triplex" units used extensively in molding plants where an accumulator was used to stabilize the momentary high-flow requirements. Present-day piston pumps include small multicylinder radial- or axial-type units of exceptionally high volumetric and mechanical efficiency. Fixed-displacement piston pumps are made but since the piston pump lends itself to variable-displacement design, by far the largest number of designs offered for sale are of this type.

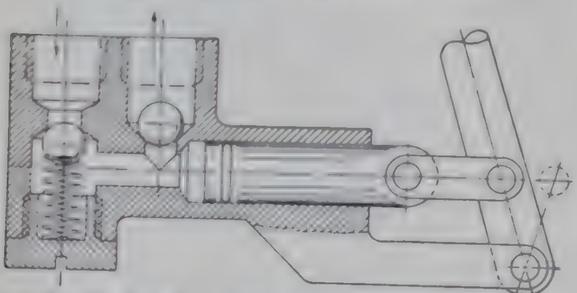

Fig. 12. Cross section through single-cylinder, single-acting, hand-operated pump.

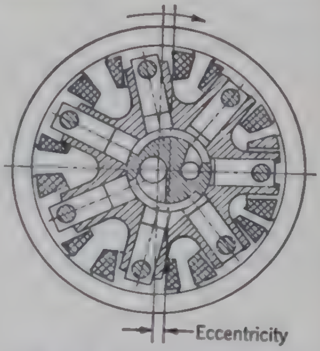

Fig. 13. Radial-piston seven-cylinder variable-displacement pump.

Radial Piston Pumps. Figure 13 illustrates a typical radial-piston seven-cylinder variable-displacement unit. The pistons are moved toward the center of rotation by cam action and returned outwardly by supercharging pressure provided by a gear pump. Centrifugal force and cams have been used for this outward motion but the supercharging design gives the highest overall efficiency. The pistons and cylinders rotate as a unit around a fixed pintle which acts as a valve as well as a bearing for the cylinder block.

Axial Piston Pumps. In axial pumps as illustrated in Fig. 14 the pistons are actuated by a crank disk. The angle between the axis of this disk and the axis of rotation of the cylinders determines the piston displacement, which may be fixed or variable.

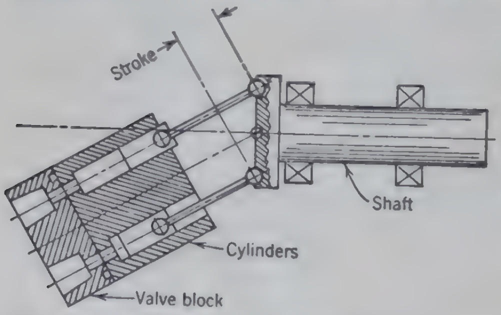

Fig. 14. Axial-piston variable-displacement pump.

The number of pistons in a pump is generally seven or nine or multiples of these numbers. Less than seven cylinders results in unsteady discharge and pressure ripples, and more than nine does not seem practical. An odd number of cylinders makes for smoother valve action, discharge, and pressure characteristics.

Piston pumps can be designed for pressures of 10,000 psi or more and are always found in high-pressure equipment.

GEAR PUMPS. The gear pump in its simplest form is the best known of all fluid-pressure pumps. It consists essentially of two meshing gears in a suitable housing containing inlet and outlet ports and connections. Each tooth in the gear acts as a piston, and each space acts as a cylinder. As the tooth pulls out of its space as a result of rotation the space is filled with fluid which is carried around the periphery of the gear confined by the housing until on the other side a tooth again enters the space and displaces the oil.

This is done in the line of the discharge port, and oil is thereby carried from inlet to discharge.

Efficiency of a gear pump is determined by the accuracy with which the various components fit together. Oil allowed to leak back through the mesh of the two gears or between the gears and the housing causes a loss and a lowering of efficiency. This flow or "slip" is usually expressed as a volume per pounds per square inch. The pump speed has little or no effect on slip, but outlet pressure has a very great effect. If s is the slip factor, the discharge of the pump can be written:

$$Q = (\text{Pump factor} \times \text{rpm}) - (s \times \text{psi}) \tag{19}$$

External Gear Pump. The designs of gear pumps may be divided into three groups: external or internal gear designs, and conjugate curve designs. Figure 15 illustrates a simple external gear pump. The pump can be run in either direction and the ports become inlet or outlet ports depending on the direction of rotation. External gear pumps are frequently made with helical or herringbone teeth in order to prevent trapping of oil in the tooth space and consequent pounding of the gears. By proper selection of materials and design proportions, gear pumps can be operated at pressures up to 2000 psi and possibly higher. The difficulty in maintaining a high volumetric efficiency precludes their use at higher pressures.

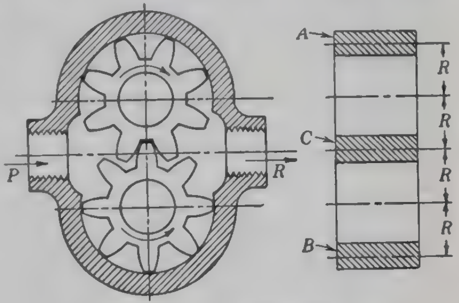

Fig. 15. Simple external gear pump.

Internal Gear Pump. Figure 16 illustrates a typical internal gear pump A pinion acts as a driver of an internal ring gear rotating in a housing. The ring gear is usually made only slightly larger in pitch diameter than the pinion gear. A crescent-shaped block fills the space between the two gears and the ports are located at the points of the crescent. These pumps find general use where compactness is required and the maximum required pressure is well under 500 psi. A modification of this design is found in the *conjugate curve pumps* illustrated in Fig. 17. In these pumps the internal member drives the outer member. The spaces between the high points of the inner member as they contact the outer conjugate curve change in volume and thereby give rise to a pumping action. Porting can be axial, as shown, or radial through holes drilled in the outer member. These pumps have been made with great accuracy, high efficiency, and for pressures up to 2000 psi. They are relatively quiet and compact.

In the *screw pump* (not illustrated) two parallel screws of meshing-tooth form are rotated in a housing closely surrounding both screws. Crescents of fluid travel axially along each screw as they are rotated together. These pumps can also be made with three screws and are made with flow from one end to the other, which might be termed single-acting, or with the flow from both ends toward the center. This latter form gives a balanced rotor with a practically zero end thrust on the bearings. Screw pumps have been made for pressures up to 1000 psi.

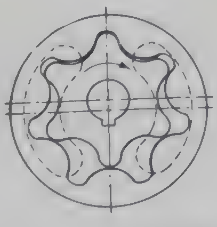

Fig. 17. Conjugate-curve internal gear pump. (Courtesy of Gerotor May Corp.)

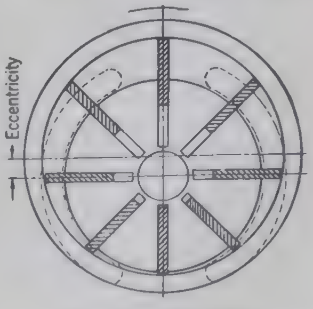

Fig. 18. Vane pump.

VANE PUMPS. Figure 18 illustrates a simple vane pump. In this design the pumping action is brought about by the change in volume of the spaces as the blades or vanes move in or out in their radial slots. Usually the fluid pressure is used to hold the vanes against the cam surface which causes their radial motion. For greatest efficiency the vanes have no radial movement while under a differential pressure. The radial motion takes place while the vane is in line with the inlet or discharge port. Vane pumps are frequently built with pressure-balanced rotors. They have two inlet and two outlet ports diametrically opposite each other. Such rotors operate with less friction and simpler bearings. Vane pumps must be carefully made of proper materials to insure minimum leakage across the barrier created by the vane. These pumps are made for pressures up to 2000 psi.

4. HYDRAULIC ACTUATORS

The simplest form of hydraulic actuator is illustrated in Fig. 19. It consists essentially of a cylinder of suitable material with an open bore into which a long piston is fitted. Actuators of this type have been designed for pressures up to several hundred thousand pounds per square inch hydraulic pressure. Actuators of this type are found in hydraulic jacks, elevators, molding presses, and wherever pressure is exerted in one direction only. The piston may carry the packing, or the end of the cylinder bore may be fitted with a gland to hold the packing. It is also practical in low-pressure (under 500 psi) designs to use this type of actuator without a packing, if means are provided to drain oil leakage back to the reservoir.

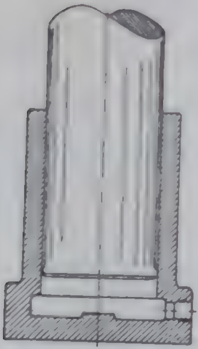

FIG. 19. Simple single-acting hydraulic actuator.

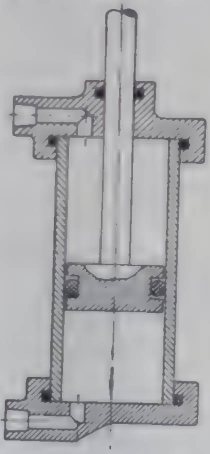

FIG. 20. Double-acting hydraulic actuator.

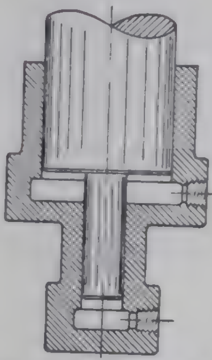

FIG. 21. Stepped-piston hydraulic actuator.

Double-acting actuators are used where force is required in two diametrically opposite directions. Such a design is illustrated in Fig. 20. For medium- and high-pressure work both the piston and the piston rod are packed. When for reasons of hydraulic balance or control the piston area in either direction must be equal, the piston rod extends through the cylinder and is packed in both cylinder caps. Double-acting cylinders have been widely used in wing flap actuators, airplane landing gear, planer and milling table feeds, etc.

Stepped Pistons. Where high actuating speed, large final force, and a relatively small pump are specified, the use of stepped or multiple-diameter pistons yields a simple solution. Figure 21 illustrates a design in which the oil is first introduced to the small cylinder actuating the piston which causes the large cylinder to act as a pump and fill with oil. When the work has been contacted, valves are shifted to connect the large cylinder to the pressure line and cut off the suction line to the large cylinder. Thus the output force is considerably increased.

FLUID MOTORS are used wherever continuous rotary motion is required. These motors may be of the **gear type** as illustrated in Fig. 15. With pressure at P and return at R, the pump will rotate in the direction of the arrows. The theoretical torque of such a motor is

$$P \times (\text{Area } A + \text{Area } B - \text{Area } C) \times R = T \tag{20}$$

and since A, B, and C are equal, this simplifies to

$$PRC = T \tag{21}$$

in which P = pressure, pounds per square inch; R = one-half center distance of gears; C = area of interference of gear OD's (tooth engagement); and T = theoretical torque.

The actual torque is considerably less than this and in well-designed and accurately fitted motors may reach 70% of theoretical. The average well-built gear pump can be used as a motor. Gear motor efficiency can be increased by proper porting and hydraulic balancing of the rotating elements. Gear motors are fixed displacement units.

PISTON MOTORS may be either axial- or radial-type units. In either case the motors may be of fixed or variable displacement. Figure 14 illustrates a design of axial motor. In this design cylinders, pistons, connecting rods, crank disk, and shaft all rotate about their respective center lines at the same speed. As the pistons in the cylinder block move about the block center line, the pistons are caused to move inwardly or outwardly by the angular displacement of the shaft center line, giving a stroke which is proportional to the sine of the angle α (Fig. 22). Angle α can be made fixed or variable as desired. The number of pistons is made either seven or nine. The torque of this type of motor is not uniform, being made up of the sum of the torques from each separate cylinder. Each cylinder through 180 degrees of shaft rotation produces torque proportional to the cosine of the angle of rotation. This can be written:

$$\text{Torque} = PAr \sin \alpha \cos \beta \qquad (22)$$

in which P = pressure of hydraulic fluid; A = area of piston; α = angular displacement of center lines of shaft and cylinder block; β = angular rotation of shaft (Fig. 22); and r = radius of crank.

The remaining 180 degrees of shaft rotation discharges the oil or fluid in the cylinder and results in a small negative torque of the same characteristics as the torque in the first 180 degrees of rotation.

The total torque of the axial piston motor can be determined by calculation of the torque produced by one cylinder at points every 10 or 15 degrees for 360 degrees. Plot these values on graph paper using torque as ordinates and degrees of rotation as abscissas. Then plot a second curve the same as the first but displaced a number of degrees from the first equal to the number of cylinders divided into 360 degrees. Do this for each cylinder and then add the curves graphically. The net result should show a torque for a seven- or nine-cylinder motor with practically no ripple.

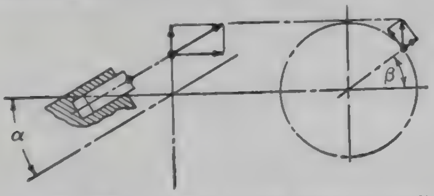

FIG. 22. Forces acting in axial piston hydraulic motor.

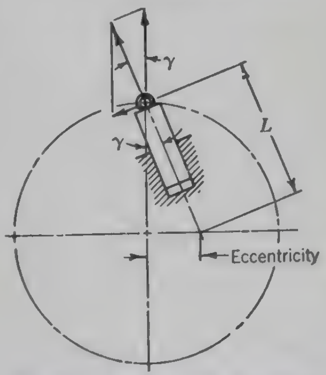

FIG. 23. Forces acting in a radial piston hydraulic motor.

Figure 13 illustrates a radial motor in which the pistons act in cylinders forming a central hub rotating on a fixed pintle. The end of the piston away from the cylinder contacts a circular ring and slides or rolls along its surface. This ring is eccentrically located with respect to the pintle center. This eccentricity may be fixed or variable. The torque of a radial piston motor is, as in the axial piston motor, equal to the sum of the torques of each piston. Figure 23 illustrates the geometry of the torque calculation. It is more complicated to calculate the torques in radial motors since the effective radius, the normal force, and the angle between the piston center line and the eccentric radius are constantly changing as the cylinder rotates around the pintle.

The torque of a radial piston motor may be written as follows for one cylinder rotating about the shaft for 180 degrees of power stroke:

$$T = APL \tan \gamma \qquad (23)$$

in which A = area of piston; P = pressure; γ = angle between radius of ring at point of piston contact and center line of piston and cylinder; and L = moment arm of piston center line.

VANE MOTORS are similar in construction to vane pumps. The best designs have balanced rotors and double ports. The torque of a vane motor is the area of the vane unbalance times its effective radius. This is most easily visualized by referring to Fig. 24 in which a simple eccentric-type motor is illustrated diagrammatically. Oil enters under pressure at P and causes rotation in the direction of the arrow. The fluid then exhausts through port E. The maximum vane area is shown at A and the minimum at B. Their effective radii to the center line of rotation are R and r respectively. It follows, therefore, that the torque can be determined from the following equation:

$$\text{Torque} = P(AR - Br) \tag{24}$$

In some vane-motor designs, area B is made zero so that eq. 24 then becomes, for single-lift unbalanced rotors,

$$\text{Torque} = PAR \tag{25}$$

When a double-lift balanced rotor is used the torque can be written:

$$T = 2PARE \tag{26}$$

in which T = torque, inch-pounds; P = pressure, pounds per square inch; A = area, square inches; R = radius, inches; and E = mechanical efficiency (usually around 70%).

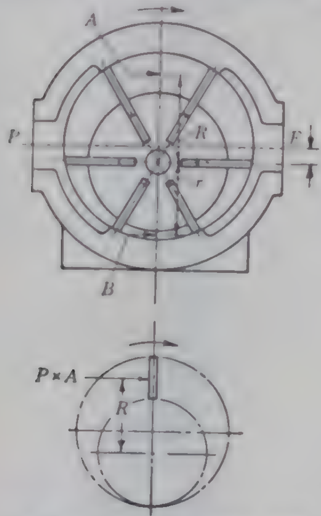

FIG. 24. Torque-producing forces in a vane motor.

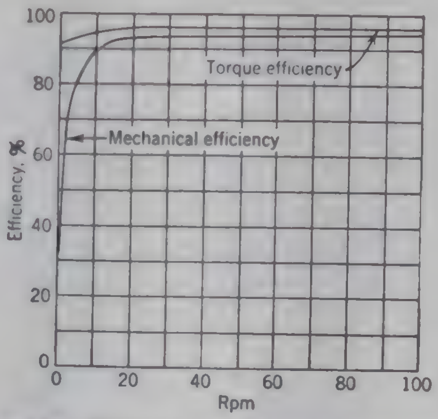

FIG. 25. Characteristics of a typical vane-type motor. (Courtesy of Sundstrand Machine Tool Co.)

The speed of any fluid motor is a function of its displacement and the amount of fluid available to operate it. Commercial motors are usually rated in theoretical displacement per revolution at zero pressure, and a curve of volumetric efficiency plotted against operating pressure is also given to enable calculations of exact requirements in terms of gallons per minute or any other convenient units to be made. Figure 25 illustrates the characteristics of a typical motor.

5. SPEED OF OPERATION

CYLINDER BORE AND STROKE. The work to be done by a hydraulic actuating cylinder may be specified exactly. This in no way limits the size and shape of the cylinder. Usually the stroke is fixed by the specifications and, unless stroke amplification or reduction through levers or gears is called for or is practical, the cylinder will be designed around this stroke. Likewise, the required force to be applied by the cylinder is usually specified. It becomes then a choice relating the force specified to the piston area and the hydraulic pressure, i.e.,

$$F = PA \tag{27}$$

There is an infinite number of combinations of P and A whose product will equal F. In general it is customary to fix an arbitrary value for P and calculate A. If the size of A then gives a reasonable and practical size to the cylinder the choice of P was a valid one. If A is too big or too small, a new value of P must be assumed and a new size A calculated. In practical machine designs pressure P can be several thousand pounds per square inch, but when P is made larger than 1000 psi the cost of the various hydraulic elements begins to rise appreciably. It is best to use as small a value of P as is consistent with the physical dimension limitations of the actuating cylinder. An allowance of 10% is usually added to the force to be exerted by a hydraulic cylinder to allow for friction of piston, rod, and packings. This is an arbitrary amount for pressures up to 1000 psi. For higher pressures, packing friction may absorb more of the available force than 10%.

CALCULATING OIL FLOW DESIRED. The flow of oil Q required to actuate a cylinder in a given time t through a stroke s when the piston area is a can be determined by the following equation:

$$Q = \frac{as}{t} \times 0.26 \tag{28}$$

where Q = gallons per minute; a = piston area, square inches; s = stroke, inches; and t = time, seconds.

ACCELERATING AND DECELERATING FLOW IN PIPES. Accelerated flow occurs when a control valve is opened and a pressure in excess of that required to balance the force of the actuator piston is available. This causes a considerable pressure drop and results in an acceleration of the fluid. Acceleration will become zero (velocity has reached a maximum) when the flow reaches the maximum delivered by the pump.

Deceleration occurs when a piston meets increasing resistance, causing a lowering of the pressure drop. Deceleration will continue until the piston load is equal to the pressure on the piston times its effective area. Another way of describing this is to say that deceleration continues as long as the pressure differential continues to decrease.

6. HYDRAULIC VALVES

DIRECTIONAL CONTROL VALVES. In designing directional control valves it is a good policy to limit the fluid velocity through the valve ports to not more than 10 ft per sec. It would be even better to reduce this to 5 if space considerations permit. Valves have been designed and used successfully with fluid velocities in excess of 10 ft per sec but at a sacrifice in power loss due to high pressure drops through the valve.

Commercial valves are available in the various types listed in the following paragraph. Wherever it seems more practical to do so, valves can be designed as integral parts of other hydraulic elements such as pumps, manifolds, and actuating cylinders.

The basic valve types are piston, plug, poppet, gate, and globe valves. *Piston* valves are used primarily when the actuating means is reciprocating. *Plug* valves are used when the actuating means is rotary, either through part or all of a revolution. *Poppet* valves are used when extreme tightness against high pressures is required. The poppets are usually cam-actuated. *Gate* valves and *globe* valves are usually used as manually operated shut-off valves.

Figure 26 illustrates the difference between two-, three-, and four-way valves. A *two-way* valve is essentially a shut-off valve and is used as such. A *three-way* valve is used to direct flow for the control of a single-acting actuator. A *four-way* valve is one used to control the action in a double-acting actuator. It can also be used to reverse the direction of rotation of fluid motors. Three- and four-way valves are designed as either closed- or open-center units (Fig. 27). In a *closed-center* valve with the valve in neutral position,

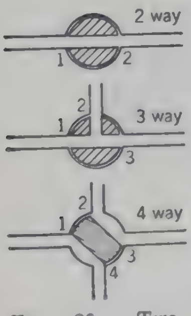

FIG. 26. Two-, three-, and four-way plug valves.

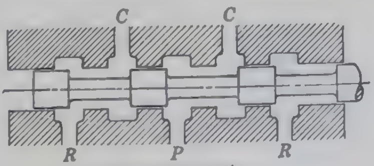
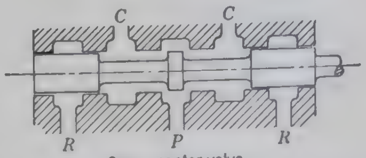


Closed-center valve



Open-center valve

FIG. 27. Closed- and open-center piston valves.

the actuator and pressure lines are blocked off; the discharge lines remain open. In an *open-center* valve, the actuator and pressure lines are interconnected; the drain lines still take care of leakage. Another design of open-center valve interconnects all lines so that the pressure is unloaded and the pump runs under substantially zero load.

MISCELLANEOUS VALVES. Sequence valves are used to guarantee the completion of one actuator cycle before another begins. Such a valve is illustrated in Fig. 28. It depends for its operation on the pressure in the hydraulic fluid. The direction of flow through the valve is shown by arrows. When inlet pressure is great enough to overcome the spring force on the valve piston, the piston will lift and allow fluid to pass through the valve to an actuator or other hydraulic device on the downstream side of the valve. As discharge pressure increases it has no effect on the piston since the piston diameter is the same as the orifice. As inlet pressure approaches discharge there is little, if any, change in the position of the piston. The valves are usually designed with a dashpot to avoid possible unstable operation of the piston. The pressure characteristics of the sequence valve must be compatible with those of the pressure regulator in the system to insure that all the oil delivered by the pump will be available in the secondary circuit. The pressure in the primary circuit must, therefore, be higher than the final secondary pressure by an amount sufficient to lift the piston to full flow position at full pump pressure against the valve spring force.

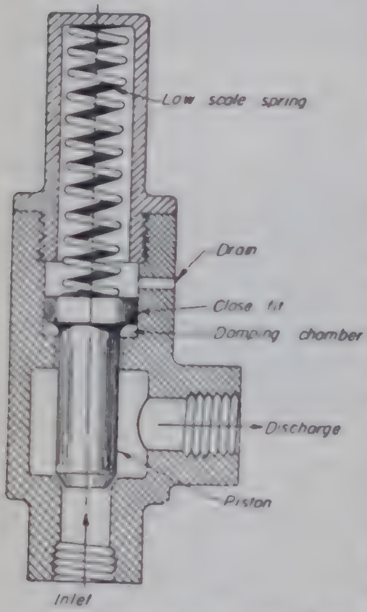


FIG. 28. Hydraulic sequence valve. (Reproduced by permission from *Machine Design.*)

Check valves are used to insure flow in a given circuit in one direction only. They should be designed to give a minimum of resistance to flow and should be simple to service. They may be of ball, poppet, or swing type. Figure 29 illustrates some common designs.

Timing or **flow-control** valves are designed to pass a specified amount of fluid in a unit of time. They are essentially refined needle valves, with or without viscosity and pressure compensation. In some designs the needle valve is replaced by a tapered orifice uncovered by a sliding piston. In calculating the basic dimensions of a timing valve the orifice coefficients of a simple orifice may be used as a first approximation. Leeway should be allowed in both directions from the specified time constant in order to insure that the range of flow through the valve will cover the desired range.

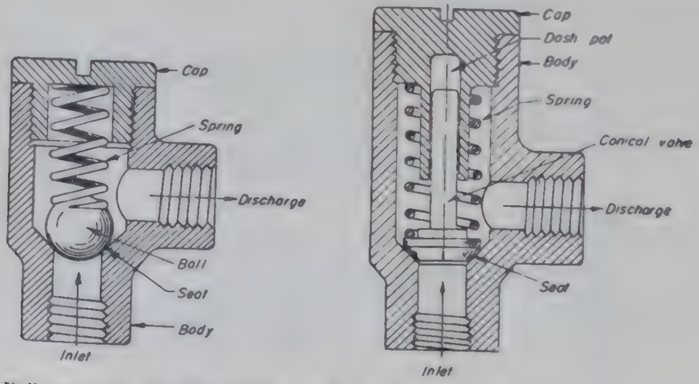

FIG. 29. Ball-type (*left*) and cone-type (*right*) check valves. (Reproduced by permission from *Machine Design*)

MEANS OF VALVE ACTUATION. Hydraulic control valves can be actuated manually, mechanically, electrically, or hydraulically.

Manually operated control valves are generally equipped with levers, push-pull handles, or handwheels to actuate either the rotary or sliding action of the piston or valve stem. The amount of force required to operate a valve depends on the refinements in the hydraulic balance and the minimizing of packing friction. It rarely needs to exceed 10 lb pull or 50 lb-in. of torque. If pressures are so high or valves so large that larger operating forces are required it becomes necessary to use power assist.

Mechanically operated valves are usually cam- or crank-operated from a suitable rotating shaft which is a part of the complete machine or unit. A series of cam-operated valves can be used to control a sequence of operations in a machine. Usually in such a case a complete revolution of the valve cam shaft completes one machine cycle. The cam shaft may be driven from the hydraulic power source by means of a suitable hydraulic motor, or it may be geared to some other rotating part of the machine of which it is a part.

Where only small forces are available to actuate a valve it is possible to use **hydraulically** operated valves in which small hydraulic cylinders actuate the main valve elements, and the flow of the hydraulic fluid to these valve-actuating (pilot) cylinders is controlled by a small direct-actuated four-way valve in which the valve-actuating force is relatively small.

Electrically operated valves are solenoid actuated where high speed and simplicity are the criteria. These valves must be so designed that the solenoid can complete its stroke and close its magnetic circuit. Otherwise, excessive noise in the solenoid and overheating will occur. Solenoid-operated valves are very bulky, particularly in the high-voltage designs, because many electrical codes require boxes to enclose connecting leads and solenoid. Solenoid valves are frequently used with micro switches to form safety interlocks to prevent hydraulic actuation before certain mechanical positioning has taken place. The micro switches are connected in series and all must be closed before the valve will function.

PRESSURE-CONTROL VALVES are designed to regulate the pressure in a hydraulic circuit or a part of such a circuit. They are so made that they prevent the hydraulic fluid from passing through them until a desired pressure has been reached. At this pressure the valve begins to open and continues to do so until the required flow is passed by the valve.

In the simple hydraulic circuit illustrated in Fig. 6 the pressure regulator, *R*, is designed to pass the entire flow from the fixed displacement pump. Such a valve is illustrated in Fig. 30. As the pressure reaches the required amount the valve piston starts to uncover the ports. This pressure is indicated by P_1 in Fig. 31. When the entire flow, Q, is passing through the valve the piston has moved up to increase the area of the ports. In order to do this the pressure had to increase to value P_2 to compress the spring a sufficient amount. This difference in pressure with flow variations is known as "regulation" or "control band." It is represented in Fig. 31 by the solid line when the valve is opening and the dotted line when closing.

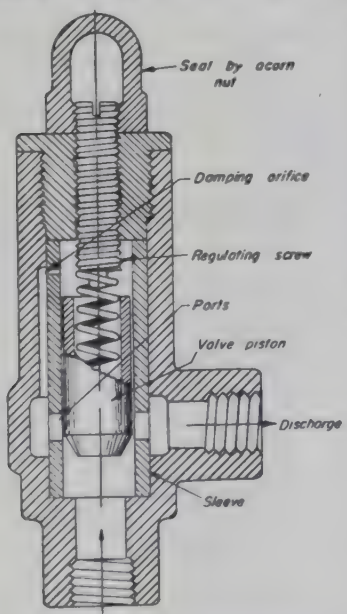

FIG. 30. Pressure-regulating valve for continuous operation. (Reproduced by permission from *Machine Design*)

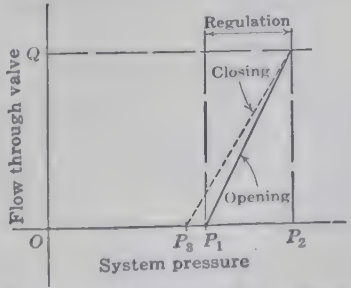

FIG. 31. Characteristics of pressure-regulating valve shown in Fig. 30. (Reproduced by permission from *Machine Design*)

Figure 32 diagrammatically illustrates a means of reducing regulation substantially to zero. Flow through the valve is regulated by the position of the main piston. The location of the main piston in relation to the orifice is achieved by controlling the pressure on top of this piston to balance the pressure in the system. A small flow of oil is by-passed through an orifice and controlled by a simple spring-loaded pilot valve. A change in flow causes a change in pressure P_1 causing the main piston to move up or down to achieve equilibrium with pressure P_3 and produce pressure P_1. Figure 33 illustrates the pressure characteristics of such a valve. As long as the flow is greater than that required by the pilot valve the output pressure will remain constant.

Figure 34 illustrates the theory of operation of a quick-acting unloading valve. Oil from the pump enters the valve at the lower left-hand corner in the diagram. It can flow either up through the check valve to the accumulator, or through the main piston valve back to the tank or reservoir. If the pressure in the accumulator is high enough, it will hold the auxiliary piston valve in the position shown, and the main valve piston will allow oil from the pump to return to the tank. As soon as the pressure in the accumulator falls to a pre-set figure the detent can no longer hold the auxiliary piston valve against the spring. It shifts with a snap action, in turn causing the main piston to shift and block the exit of oil from the pump, thereby causing the oil to flow to the accumulator and increase pressure in the hydraulic circuit.

Figure 35 illustrates a form of pressure-reducing valve. These valves are designed to reduce the hydraulic pressure from a high pressure to a lower pressure, and to maintain the lower pressure regardless of flow. The regulating spring holds the piston in the open position until pressure builds up against the diaphragm to overcome the spring force and close the valve piston. As flow varies, the position of the piston will adjust itself to maintain equilibrium. This valve is used as illustrated in Fig. 11.

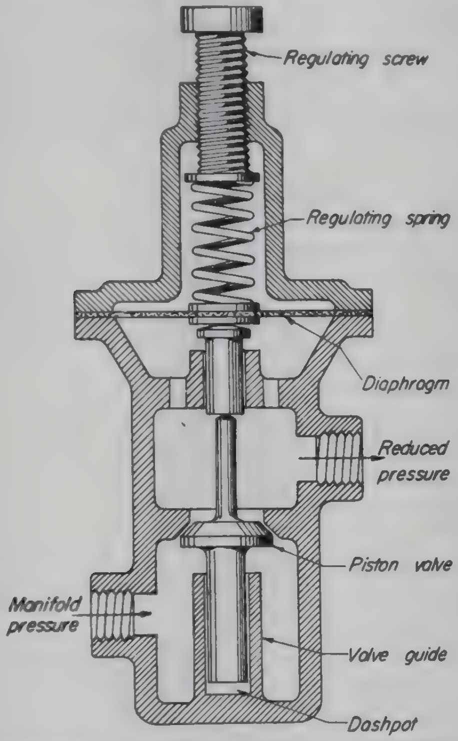

FIG. 35. Pressure-reducing valve. (Reproduced by permission from *Machine Design*)

Vibration or "whistling" is a common fault of simple pressure regulators. Means must be provided to cause damping of the valve vibrations, which is usually accomplished by the use of suitable dashpots.

7. HYDRAULIC PIPING, FITTINGS, AND FLUIDS

HYDRAULIC PIPING may be divided into two major groups, rigid and flexible. **Rigid piping** may be steel or iron pipe, either seamless or welded, using standard screw thread fittings. It may also be this same steel or iron pipe using brazed or welded fittings. Most modern machines use steel, brass, or aluminum tubing with a minimum of fittings, bending the tubing with hand or machine-bending tools. Table 1 gives a list of common tube sizes, standard bending radii, and other pertinent data.

Table 1.

Tube, OD	Wall	Maximum Flow, gal per min	Bending Radii to ℄ of Tube	
			Hand Bending	Machine Bending

1 1/2	.095	80.0	.....	5
1 3/4	.095	100.0	.....	7

FITTINGS. A wide variety of hydraulic tubing fittings have been developed and are commercially available. Figure 36 illustrates various combinations of fitting ends. They are available in most of the commercial designs. Figure 37 illustrates two designs of hydraulic pressure fittings: one, a flare type in which the tube end must be flared when the fitting is assembled, the other, a ferrule type in which the tube needs only to be cut to length.

Flexible tubes are available for working pressures up to 12,000 psi. These high-pressure tubes are limited in diameter to relatively small bores. They gain their strength from built-in steel braid. Flexible tubes are in general not readily flexed when under pressure and as a result their life is short. It is best to use a minimum of flexible tubing in hydraulic machine design. Fittings on the flexible tubing are generally swaged or clamped on and the tubing will burst before a well-mounted fitting blows off. Fittings are available to match most commercial rigid tubing fittings. Standard pipe thread fittings are also available.

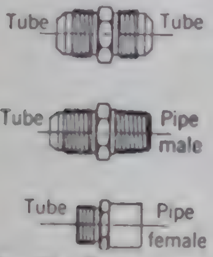

FIG. 36. Typical combinations of fitting ends.

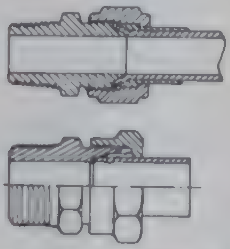

FIG. 37. Flare-type fitting (Parker Appliance Co.), upper view; ferrule-type fitting (Weatherhead Co.), lower view.

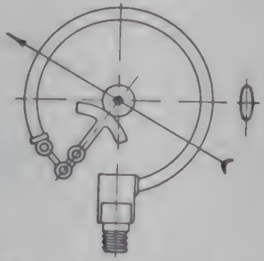

FIG. 38. Bourdon tube pressure gage.

PRESSURE INDICATORS. Hydraulic pressure is generally measured by a pressure gage consisting essentially of a bourdon tube and a suitable means for converting the deflection of the bourdon tube into motion of a pointer along a scale. For moderate pressure, the bourdon tube is made of steel. Figure 38 illustrates the principal parts of a simple pressure gage. Pressure gages should be calibrated on a dead-weight testing device.

The deflection under pressure of bellows or diaphragms can also be used as a means for measuring pressure. Here again, the deflection is converted by mechanical means to a suitable pointer and scale.

Pressure gages of the bourdon tube or bellows design are suitable only for static pressure measurements and for the measurement of relatively slow pressure changes. The lag and damping effect of the masses in the pointer actuating mechanism prevent rapid pressure changes from being indicated, and the rapid pointer motion cannot be followed by the human eye.

For measuring dynamic pressure some means of recording the pressure fluctuations is necessary. The best way of doing this is by a gage measuring the deflection in some part of the hydraulic circuit and recording this change on an oscillograph. (See Section 18, Article 7.)

HYDRAULIC FLUIDS. **Water** was one of the most widely used hydraulic fluids in early hydraulic machinery. It has the advantage of being inexpensive, readily available, and it has a very flat viscosity curve. Its disadvantages are that it is a poor lubricant, is corrosive to steel and iron, and cannot be used below 32°F unless additives are used. In spite of its disadvantages it is still used in large central hydraulic pressure systems, such as are found in rubber plants and plastic molding plants.

Mineral oil has displaced water as a hydraulic fluid in hydraulic machine design. Mineral oil is a good lubricant, gives good packing life, and (if proper oils are selected) can be used successfully at subfreezing temperatures. Mineral oil has the disadvantage of having poor temperature-viscosity characteristics. Various additives have been included in mineral oils to improve their viscosity characteristics. They are reflected in the flatter curves illustrated in Fig. 2.

Organic oils have received wide use as hydraulic fluids, notably in automobile brakes. This has been brought about by the use of natural rubber for lines and packings. Natural rubber is not affected by organic oils. These oils oxidize rapidly and must have additives to minimize these tendencies.

In recent years **synthetic oils**, notably the silicones, have been offered for hydraulic service. They are excellent for this use but cost more than mineral oils. Their advantage lies in their freedom from sludge-forming components and their very flat viscosity characteristics.

HYDRAULIC FLUID FILTERS. In order to insure minimum wear and long life of the various elements in a hydraulic circuit it is necessary to maintain absolutely clean fluid. Clean fluid also helps to maintain reliable action of controls and other closely fitted parts. Small particles of dirt can cause malfunctions and sticking of valve stems and poppets.

For best results the so-called micronic filters will be required. These filters will pass no particles over a few microns in major dimension. They must be large enough in area to pass the entire flow of oil with only a few pounds per square inch pressure drop across the filter element.

So-called edge-type filters are next in cleaning ability. They will pass particles substantially the same size as the plate or flat wire spacing, depending upon which type is used. Commercial filters are usually constructed with a by-pass set at a pressure below which the pump should operate. If the filter plugs up, the by-pass will allow the oil to flow past the filter without building up a dangerous pressure. Filters are made to be used in the pressure side of a circuit as well as in the suction line to the pump. If the tank or reservoir is not tightly sealed, dirt can enter it, and it is best then to have the filter on the suction pipe. If, on the other hand, the entire hydraulic system is tightly sealed the filter may be installed in any part of the circuit through which substantially all the oil is flowing.

Filters should be cleaned regularly and new elements installed. Self-clearing types of filters are not as good as the micronic designs. Great care should be taken in the assembly of hydraulic circuits to prevent foreign material from getting into them. This will minimize the work the filter will have to do.

HYDRAULIC FLUID RESERVOIR. The tank or reservoir is an important detail of a hydraulic circuit that is frequently neglected by the designer. It should contain enough oil so that heat generated in the circuit can be dissipated adequately by radiation and conduction. In general, if the capacity of the tank in gallons is equal to the number of gallons pumped in one minute and the tank is not too cubical in design enough tank surface will be available for good radiation. This relation will be valid only for pressures of 1000 psi or less.

The tank should if possible be compartmented. Oil returned to the tank should enter one compartment and then should flow over a dam and under a baffle to a second compartment containing the suction line near the bottom. The purpose of the dam and baffle is to surface entrained bubbles of air and to present only solid oil to the pump suction line. Means should be provided to clean out the tank and to drain off oil from its lowest point.

GEARING

1. THE INVOLUTE SYSTEM OF TOOTHED WHEEL GEARING

The data in this section are limited to toothed wheel gearing of the involute form. Since the earliest appearance of geared mechanisms, when wooden pegs were set in the periphery of wooden wheels, many curves have been used as the basis for the forms of the gear teeth. In all cases curves were selected to provide constant relative velocity of the gear tooth faces (Fig. 1). The essential property common to these curves is such that when two teeth are in contact, the common normal to the tooth curves at their point of contact must pass through the point of contact of the two pitch circles.

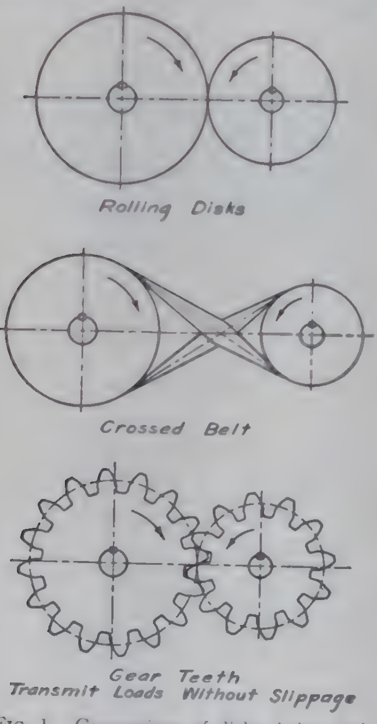

FIG. 1. Comparison of disks, belts, and gearing.

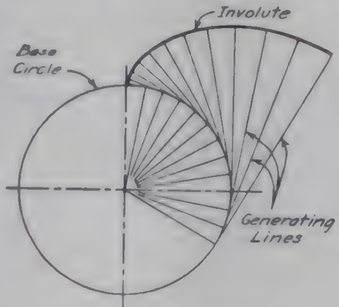

FIG. 2. Typical involute curve generation.

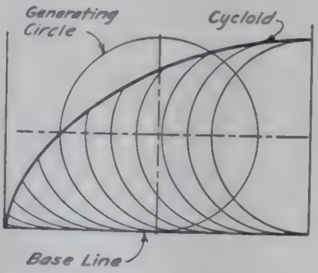

FIG. 3. Generation of cycloidal curve for a rack.

The introduction of gear-cutting machinery and the resultant wider use of toothed gearing to transmit heavier loads at ever-increasing speeds resulted in a gradual transition of tooth forms to the point where the involute curve (Fig. 2) is now considered to be the most practical curve for gear teeth. A few applications still employ curves of the cycloidal type (Fig. 3), and the pin-tooth type may be found in clock mechanisms, but general industry today relies on the involute curve system.

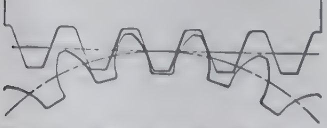

FIG. 4. Straight-sided rack used with involute gearing.

The basic rack form of the involute gear tooth has straight lines and is consequently relatively simple to produce. Present-day power transmission demands precision gearing, and the involute system based on a straight-sided rack (Fig. 4) provides a means of controlling quality to meet exacting requirements. In addition, gears of the involute type may be operated on variable center distances without affecting the theoretically correct action of the teeth in mesh (Fig. 5).

The above factors, and others, have resulted in universal acceptance of the involute curve system as the basis for gearing. The American Standards Association (ASA), as well as the American Gear Manufacturers Association (AGMA), uses the involute system in its standardization program.

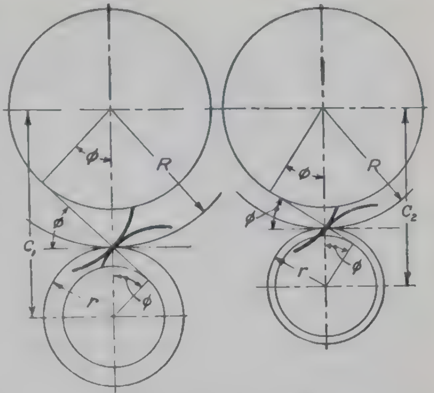

Fig. 5. Effect of varying center distance on involute action. Pressure angle changes but action is still correct.

2. NOMENCLATURE AND GEOMETRY

The technological advancement in the art of gearing has created its own unique division of mathematics. The AGMA has established a standard nomenclature for gearing and in collaboration with the ASA has arrived at a series of engineering symbols with the object of providing a common ground for all those interested in this specialized field of power transmission.

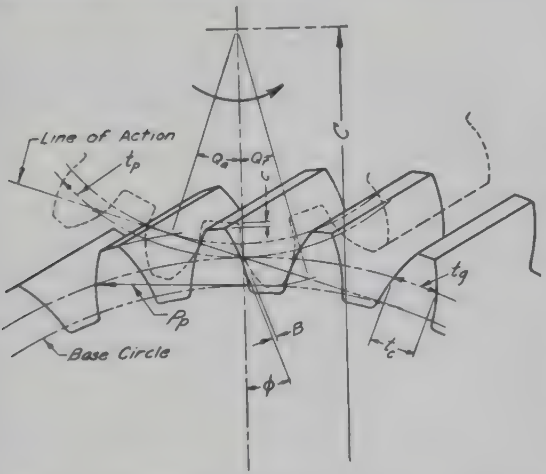

Fig. 6. Nomenclature and geometry terms for gearing.

The following more commonly used definitions are from the AGMA data (Figs. 6 and 7).

PITCH DIAMETER (*D*, *d*) is the diameter of the pitch circle. Unless otherwise specified, it is the *standard pitch diameter* obtained by dividing the number of teeth by the diametral pitch or by multiplying the circular pitch by the number of teeth divided by π (3.1416). In parallel-shaft gears, the pitch diameters can be determined directly from the number of teeth and the center distance. *Operating pitch diameter* is the pitch diameter at which the gear operates. *Generating pitch diameter* is the pitch diameter at which a gear is generated. In bevel gears the pitch diameter is understood to be at the outer ends of the teeth unless otherwise specified.

ADDENDUM (*a*) is the height by which a tooth projects beyond the pitch circle; it is also the radial distance between the pitch circle and the addendum circle.

DEDENDUM (*b*) is the depth of a tooth space below the pitch circle; it is also the radial distance between the pitch circle and the root circle.

CLEARANCE (*d*) is the amount by which the dedendum in a given gear exceeds the addendum of its mating gear.

ROOT DIAMETER (D_R, d_R) is the diameter of the root circle.

THE BASE CIRCLE is the circle from which involute tooth profiles are derived.

WORKING DEPTH (h_k) is the depth of engagement of two gears, that is, the sum of their addendums.

CENTER DISTANCE (*C*) is the distance between the parallel axes of spur gears and

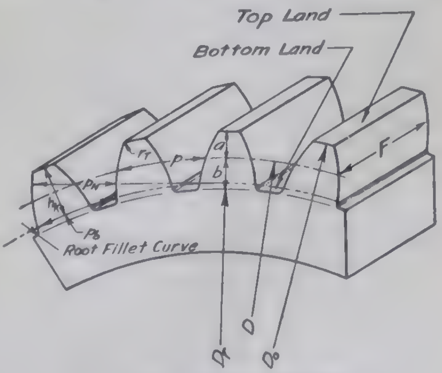

Fig. 7. Gear tooth terminology.

parallel helical gears or the crossed axes of crossed helical gears and worm gears. Also it is the distance between the centers of the pitch circles.

OUTSIDE DIAMETER (D_o, d_o) is the diameter of the addendum (outside) circle. In a bevel gear it is the diameter at the crown circle. In a throated worm gear it is the maximum diameter of the blank.

CHORDAL THICKNESS (t_c) is the length of the chord subtending a circular-thickness arc. **CIRCULAR THICKNESS** (t_t, t_n) is the length of arc between the two sides of a gear tooth on the pitch circle unless otherwise specified.

The **ROOT FILLET CURVE** is the concave portion of the tooth profile where it joins the bottom of the tooth space.

TOOTH TIP RADIUS (r_T) is the radius of the circular arc used to join a side-cutting edge and an end-cutting edge in gear-cutting tools.

PRESSURE ANGLE (ϕ) is the angle between a tooth profile and the radial line at its pitch point. Unless otherwise specified, it is the standard pressure angle at the standard pitch diameter. The *operating pressure angle* is the pressure angle at the pitch diameter at which the pair of gears operates. The *generating pressure angle* is the pressure angle at the pitch diameter at which the gear is generated. Still other pressure angles are used in gear calculations. In various gear-cutting tools the pressure angle is the angle between the cutting edge and the principal direction. For a spur gear or straight bevel gear which has tooth profiles only in the transverse section the general term "pressure angle" may be used without qualifications.

PROFILE RADIUS OF CURVATURE (ρ_p) is the radius of curvature of a tooth profile, usually at the pitch point or a point of contact.

CIRCULAR PITCH (p) is the distance along the pitch circle or pitch line between corresponding profiles of adjacent teeth.

ANGLE OF APPROACH (Q_a) is the arc of the pitch circle through which a tooth profile moves from its beginning of contact until the point of contact arrives at the pitch point.

ANGLE OF RECESSION (Q_r) is the arc of the pitch circle through which a tooth profile moves from contact at the pitch point until contact ends.

A POINT OF CONTACT is any point at which two tooth profiles touch each other.

The **TOOTH SURFACE** forms the side of a gear tooth.

TOP LAND is the surface of the top of a tooth.

BOTTOM LAND is the surface at the bottom of a tooth space adjoining the fillet.

BACKLASH (B) is the amount by which the width of a tooth space exceeds the thickness of the engaging tooth on the pitch circles. As actually indicated by measuring devices, backlash may be determined variously in the transverse, normal, or axial planes, and either in the direction of the pitch circles, or on the line of action. Such measurements should be corrected to corresponding values on transverse pitch circles for general comparisons.

Table 1. Relation of Dimensions of Parts of Gears, Composite and Full-depth Systems

Notations: P = diametral pitch; p = circular pitch; N = number of teeth; D = pitch diameter; D_o = outside diameter; a = addendum; t = thickness of tooth at pitch line; r = root; c = clearance; W = working depth; H = whole depth.

P	W	$W = 2 \div P$	p	c	$c = 0.05p$
P	H	$H = W + c = 2.157 \div P$	t	c	$c = 0.1t$
P	c	$c = 0.157 - P$			
t	c	$c = 0.1t$			

The **LINE OF ACTION** is the path of contact in involute gears. It is the straight line passing through the pitch point and tangent to the base circles.

FACE WIDTH (F) is the length of the teeth in an axial plane.

BASE PITCH (p_b) in an involute gear is the pitch on the base circle or along the line of action. Corresponding sides of involute gear teeth are parallel curves, and the base pitch is the constant and fundamental distance between them along a common normal in a plane of rotation.

CONTACT RATIO (m_c), which is the ratio of the arc of action to the circular pitch, is sometimes thought of as an average number of teeth in contact. For involute gears, the contact ratio is obtained most directly as the ratio of the length of action to the base pitch.

DIAMETRAL PITCH (P or P_d) is the ratio of the number of teeth to the number of inches in the pitch diameter.

BRITISH MODULE PITCH (m) is the ratio of the pitch diameter in inches to the number of teeth. It is the reciprocal of the diametral pitch. **METRIC MODULE PITCH** (m) is the ratio of the pitch diameter in millimeters to the number of teeth.

GEAR RATIO (m_G) is the ratio of the larger to the smaller number of teeth in a pair of gears.

3. GEAR TOOTH FORM SYSTEMS

Within the broad terminology of the involute system, there are many variations possible in the tooth form produced. Many applications in industry employ special combinations of pressure angles or variable proportions of addendum and dedendum to achieve the ultimate in performance. The factors governing them are so varied as to make it impossible to delineate them clearly here. The general run of gear requirements can usually be satisfied by one of the following four systems which have been standardized by the ASA under the joint sponsorship of the AGMA and the ASME:

A. The 14 1/2-degree composite system.
B. 14 1/2-degree full-depth tooth system.
C. The 20-degree full-depth tooth system.
D. The 20-degree stub-tooth system.

In the following paragraphs on the tooth form systems, the data given apply to the finished form. Manufacturing procedures such as grinding and shaving often require special tooth forms to be used in the primary production stages to allow finish stock on certain portions of the profile.

14 1/2-DEGREE COMPOSITE SYSTEM, developed originally by Brown & Sharpe Manufacturing Company for use with its formed gear-milling cutters, has been commonly known as the Brown & Sharpe 14 1/2-degree involute system. It has proved to be a very satisfactory gear-tooth system for general purposes. Figure 8 shows the form of the basic rack and the standard tooth proportions. Gears of this system are generally produced by formed milling cutters, but hobs made to this basic rack form are sometimes used.

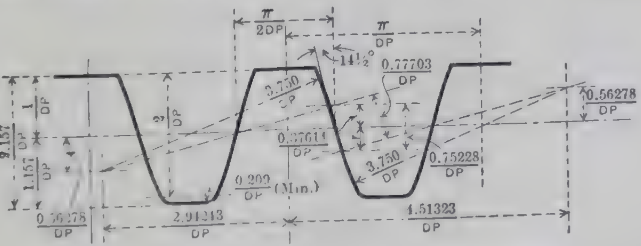

FIG. 8. Basic rack for 14 1/2-degree composite system.

Formed Milling Cutters for 14 1/2-Degree Composite System. Theoretically a different cutter is required for every different diameter of gear, even though the pitch remains the same. In practice, however, it has been found that the same cutter can be used for several sizes of gears having the same pitch, without serious error (see Table 2). By this plan 8 cutters will cut all gears of 12 teeth and over, of any one pitch. Thus, it takes 8 cutters to cut all 4-pitch gears of 12 teeth or more. A No. 8, 5-pitch cutter cuts only 5-pitch gears having 12 or 13 teeth. On each cutter the numbers of teeth at the limits of its range and the number of the cutter are stamped. When required, the error introduced by the use

Table 2. List of Gear Cutters and Numbers of Teeth Cut

(Brown & Sharpe Manufacturing Co., Providence, R. I.)

Cutter No.	No. of Teeth	Cutter No.	No. of Teeth	Cutter No.	No. of Teeth	Cutter No.	No. of Teeth
1	135–rack	3	35–54	5	21–25	7	14–16
2	55–134	4	26–34	6	17–20	8	12–13

of range cutters can be minimized by cutting the teeth in mating gears to slightly different depths. See Ref. 1, Chapter IV.

14 1/2-Degree full-depth tooth involute system was developed for use with gear hobs, for both spur and helical gears. As the useful tooth form cannot exist below the base circle of the involute form, this system should not be used for small numbers of teeth unless a suitable change is made in the tooth proportions of mating gears. See Ref. 1, Chapter V. This system has proved to be a satisfactory form for general purposes for both spur and helical gears. The form of the basic rack and the standard tooth proportions are shown in Fig. 9. The standard tooth proportions of this system are the same as those for the 14 1/2-degree composite system. (See Table 3.) When the number of teeth in any gear of this system is less than 35, undercut will be present. When the number of teeth is less than 22, the amount of undercut may be enough to reduce the angle of action appreciably.

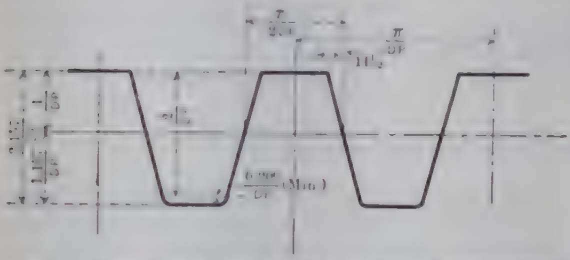

Fig. 9 Basic rack for 14 1/2-degree full depth involute system.

20-DEGREE FULL-DEPTH TOOTH INVOLUTE SYSTEM was developed for use with hobs and also for use with Fellows gear shapers. The increased pressure angle results in stronger tooth forms, and its use is rapidly increasing for general industrial purposes.

---

* The term Diametral Pitch is used up to 1 DP inclusive and the term Circular Pitch is used for 3 in. CP and over.

† A suitable working tolerance should be considered in connection with all minimum recommendations.

‡ Minimum clearance refers to the clearance between the top of the gear tooth and the bottom of the mating gear space, and is specified as minimum to allow for necessary cutter clearance for all methods of producing gears.

It is also widely used in automotive construction. The form of the basic rack and the standard tooth proportions are shown in Fig. 10. The standard tooth proportions of this system are the same as those for the 14 1/2-degree composite system. (See Tables 1 and 3.) When the number of teeth in any gear of this system is less than 17, undercut will be present. When the number of teeth is less than 14, this undercut may be enough to reduce the angle of action appreciably.

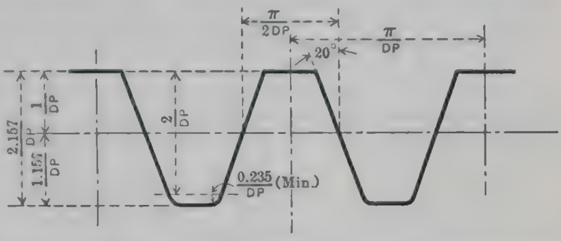

Fig. 10. Basic rack for 20-degree full depth involute system.

20-DEGREE STUB-TOOTH SYSTEM originally was developed for heavy-duty, generally slow-speed, machinery applications in order to obtain the strongest practical tooth forms. It was later adopted for automotive uses where the numbers of teeth were small. Several different stub-tooth systems, differing but slightly from each other, have been developed. The basic rack form and tooth proportions shown in Fig. 11 will interchange and operate with all of the 20-degree stub-tooth systems in general use, the only difference being in the amount of clearance. The dimensions of the tooth parts of this system are given in Table 4.

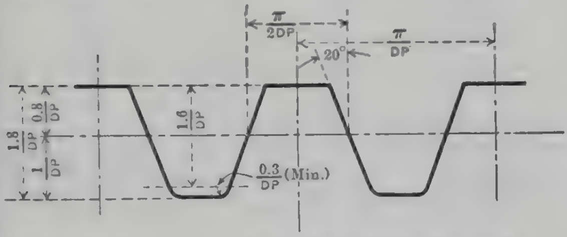

Fig. 11. Basic rack for 20-degree stub involute system.

FELLOWS STUB-TOOTH GEAR SYSTEM. The 20-degree stub-tooth gear system developed by the Fellows Gear Shaper Company has been widely used for automobile transmissions. The proportions of the teeth are based on two diametral pitches (Fig. 12), one of which is used to obtain the dimensions of the addendum and dedendum, whereas the other is used for the dimensions of the pitch circle and tooth thickness. These gears are designated by a fraction, as 4/5, 10/12 pitch, etc. The numerator designates the pitch determining the number of teeth and tooth thickness. The denominator designates the pitch determining the height of the teeth. The clearance is 0.25/diametral pitch. **Table 5 gives dimensions of Fellows stub-tooth gears.**

Table 5. Fellows Stub-tooth System

LONG AND SHORT ADDENDUM GEARING. In the discussions of the 14½-degree and 20-degree full-depth systems, mention was made of the possibilities of undercut existing in low numbers of teeth. Varying proportions of addendum (Fig. 13) are commonly resorted to in order to obtain the maximum efficiency of the tooth form selected.

FIG. 12. Basic rack tooth form proportions for Fellows stub system.

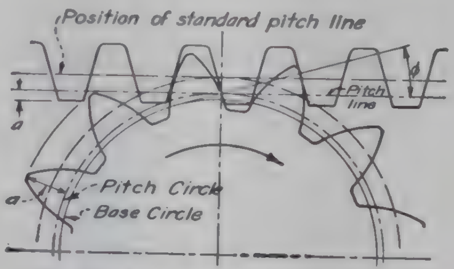

FIG. 13. Long and short addenda teeth.

Where the tooth form selected indicates undercutting, decreasing the outside diameter of the gear until it falls inside the point of tangency of the line of action with the pinion base circle and increasing the outside diameter of the pinion a like amount will eliminate the condition. The teeth in the modified blanks can be readily produced with standard hobs and assembled on standard centers.

Additional advantages in modifying the addendum proportions include increased strength of the pinion teeth and smoother tooth action.

METRIC OR MODULE SYSTEM. The word "module" is sometimes used in connection with the British module term, which is the ratio of the pitch diameter in inches to the number of teeth. (It is the reciprocal of the diametral pitch.) Most generally, it is used to designate the metric system.

Metric or module system of gear teeth is a system in which the diametral pitch is not used, but instead the dimensions of gear teeth are expressed by reference to the module of the gear. The module in this case is equal to the pitch diameter in millimeters divided by the number of teeth in the gear. For example, if the pitch diameter of a gear is 50 mm and the number of teeth is 25, the module equals 50 ÷ 25 = 2. Table 6 gives a comparison between the module and the corresponding diametral pitch of gears.

The module is also equal to the circular pitch in millimeters divided by 3.1416. Either rule gives the same result. For changing module pitch to circular pitch: p = module × 0.123684792. For changing module pitch to diametral pitch: $P = 1 \div$ (module × 0.03937).

Table 7 shows equivalents of diametral, circular, and module pitches. Standard pitches are shown in bold type and the equivalents in light-face type.

4. SPUR, HELICAL, AND HERRINGBONE GEARING

The usual types of gearing connecting parallel shafts may be described as having spur, single helical, double helical, or herringbone teeth (Fig. 14), and the gearing may be either external or internal. The process used to produce the gear teeth may require slight variations in construction, but the involute curve and a common basic rack provide interchangeability.

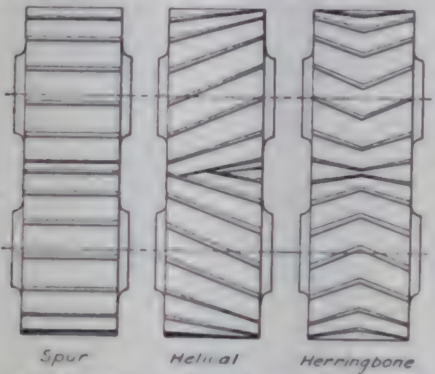

FIG. 14. Types of gears for parallel shafting.

SPUR GEARING is the term for designating designs using gear teeth whose faces are parallel to the axis of the blank. One of the principal advantages in spur gearing is its ability to transmit motion without end thrust, and without axial displacement limits as long as the face width in contact meets the load-carrying requirement.

The contact conditions in straight spur gearing are such that the load is carried on an area (Fig. 15) equal to the face times the width of the compressively flattened area parallel to the axis. Generally speaking, the number of teeth in contact in the plane of rotation may be assumed to divide the total transmitted load among several teeth at the point of transfer of the contact from one tooth (Fig. 16) in contact to two teeth in contact. The entire load is applied to one tooth.

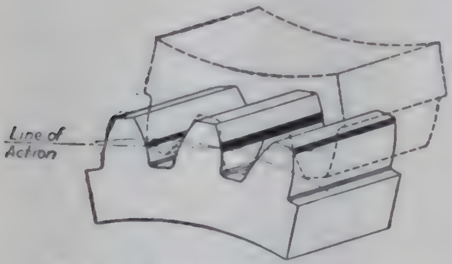

FIG. 15. Load zones in spur gearing.

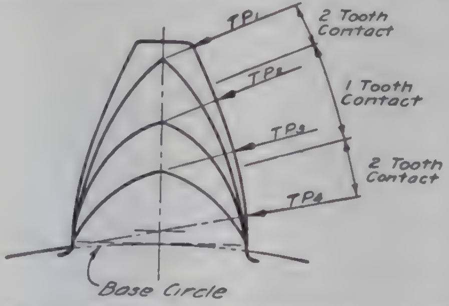

FIG. 16. Progression of tooth contact and load zones.

In large slow-moving spur gearing, a staggered tooth arrangement (Fig. 17) is sometimes resorted to in an effort to divide spacing errors and obtain smoother tooth-to-tooth action. With modern methods and machinery, this load transfer condition is minimized through control of tooth profiles, spacing, and backlash.

It is apparent that the problem of maintaining accuracy of tooth forms is simpler in straight spur gearing than in others; consequently many precision gear trains employ this type of gearing in preference to other types.

HELICAL GEARING. If we were to take an infinite number of spur gears of infinitesimal thickness and place them together with each lamination uniformly displaced ahead of the preceding one, we would have a "stepped gear" approaching helical gear construction. If the position of the first lamination is such that it is just entering contact, the successive laminations will be found to be in contact in uniformly advancing positions along the line of action.

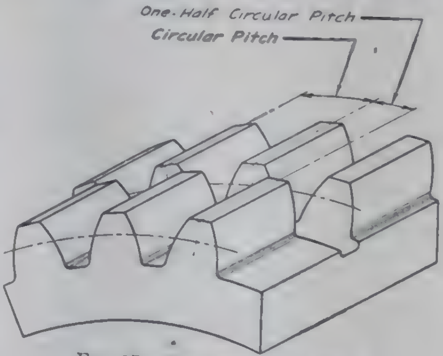

FIG. 17. Staggered spur teeth.

Modern helical gears, made popular through improved gear-cutting machinery and economical thrust bearings, utilize this improved contact condition by twisting the el-ments of a spur-gear tooth uniformly across the face into a helix. Helical gears using the same basic spur gear normal section will have varying pressure angles, depending on the helix angle. The angle of the tooth (at its pitch line) with the axis of the gear is called the helix angle (Fig. 18).

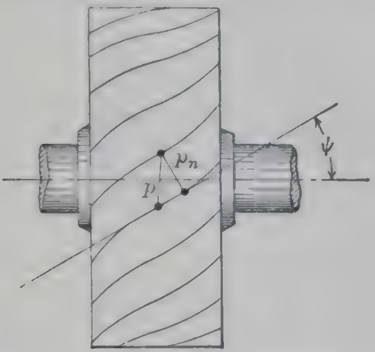

Fig. 18. Helix angle ψ, circular pitch p, normal circular pitch p_n.

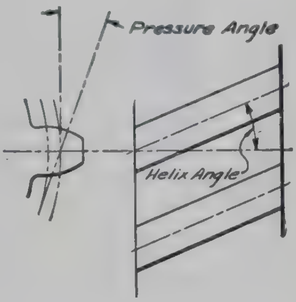

Fig. 19. Helical gear spur proportions in plane of rotation.

Helical gears may be cut with spur-gear dimensions in the plane of rotation (Fig. 19), and thus be interchangeable on centers with spur gears of the same pitch and numbers of teeth, or spur-gear cutters may be used to produce the spur-gear tooth parts in the normal plane (Fig. 20), thereby increasing the diameters, tooth thicknesses of the gears, and the center distance by relation to the helix angle.

The same basic rack forms are used for spur gears and for helicals, although special forms and proportions are often used for specific application conditions. Although the conjugate action between the tooth profiles in the plane of rotation is identical to that on spur gears, there is, in addition, a tendency for continuous action along the helices of mating teeth. While it has been shown that any helix angle develops this tendency, it is obvious that as the helix angle increases, more teeth are brought into the zone of action, and the action becomes smoother.

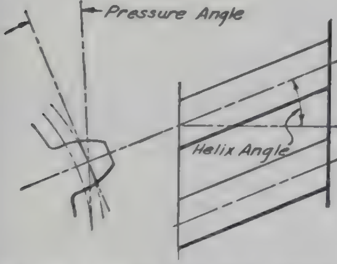

Fig. 20. Helical gear spur proportions in normal plane.

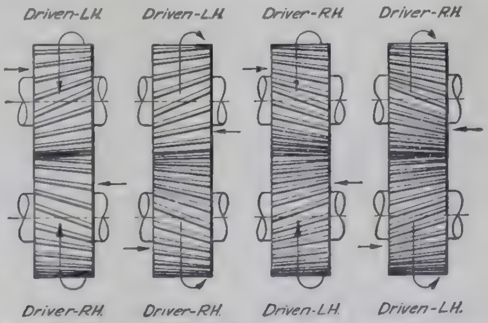

Fig. 21. Thrust conditions in helical gears. Arrows show direction of thrust.

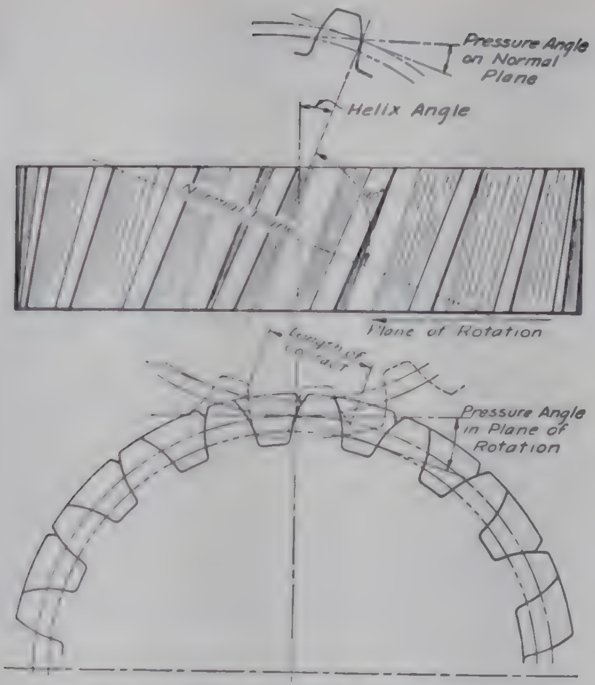
Since single helical gears develop an end thrust in proportion to the tangent of the helix angle (neglecting friction), it is customary to use reasonably low helix angle ranges (under 25 degrees) unless the developed thrust is being used to offset external reactions. The direction of the thrust depends on the hand of the helix and the direction of rotation (Fig. 21).

Formulas for helical gearing are the same as for spur gearing where the cutters used produce the spur-gear tooth proportions in the plane of rotation (Fig. 22). Where tooth proportions in the plane normal to the helix are identical to spur teeth, the following formulas may be used to determine the plane of rotation proportions:

$$D = \frac{N}{P_{nd}} \cos \psi$$

where D = pitch diameter, N = number of teeth, P_{nd} = normal diametral pitch, and



Pressure Angle on Normal Plane
Helix Angle
N
Plane of Rotation
Length of Contact
Pressure Angle in Plane of Rotation

FIG. 22. Helical gear nomenclature.

ψ = helix angle. Also the diametral pitch in the plane of rotation is

$$P_d = \frac{P_{nd}}{\cos \psi}$$

and the center distance of a pair of helical gears is

$$C = \frac{N_G + N_p}{P_{nd} \cos \psi}$$

Milled Helical Gears. Helical gears may be produced by milling on a milling machine with the same formed milling cutters as are used for spur gears. The general formulas required for such helical gears are shown in Table 8.

Table 8. General Formulas for Helical Gearing

To Find	Symbol	Formulas
Number of teeth in gears *	N_G, N_p	$N = DP_n \cos \psi$
Center distance	C	$C = (N_G + N_p)/P_{nd} \cos \psi$
Circular pitch (circumferential)	p	$p = 3.1416D/N = p_n/\cos \psi$
Normal circular pitch	p_n	$p_n = p \cos \psi$
Diametral pitch	P	
Normal diametral pitch	P_{nd}	$P_{nd} = 3.1416/p_n$ (pitch of cutter)
Pitch diameter	D	$D = pN \div 3.1416 = p_nN/3.1416 \cos \psi = ND_o \div (N + 2 \cos \psi)$
Outside diameter	D_o	$D_o = D + 2a = D + (2/P_{nd})$
Angle of teeth with axis	ψ	$\cos \psi = N \div (P_{nd}D)$
Thickness of tooth	t	$t = p_n/2$
Addendum	a	$a = p_n/3.1416 = 1/P_{nd} = 1/2(D_o - D)$
Whole depth of tooth	H	$H = 2a + 0.1t$
Number of teeth marked on cutter when teeth are to be cut in milling machines †	T	$T = (N/\cos^3 \psi) + (p_n \times D_c \times \tan^2 \psi)$ ‡
Lead (exact) of spiral on pitch surface	L_1	$L_1 = N_p/\tan \psi = N \times 3.1416/P \tan \psi$
Lead (approx.) of spiral on pitch surface	L_2	$L_2 = 10WG_2 \div SG_1$ §

* The subscripts G and p appearing in notations refer to gear G and pinion p, respectively.

† Cutters of composite system. See Table 2.

‡ D_c = diameter of milling cutter to middle of tooth profile.

§ W = number of teeth on worm; G_1, G_2 = teeth in first and second gears on stud, respectively; S = teeth in gear on screw, on spiral heads of Brown & Sharpe milling machines. The formula may not apply to spiral heads of different construction.

HERRINGBONE GEARING is sometimes called double helical gearing since the construction of a herringbone gear is essentially the same as two single helical gears having opposite hand helices and placed back to back. Herringbone gearing has various constructions. The gear tooth faces may be continuous, separated only sufficiently for cutter clearance, widely separated to span secondary gear trains, or staggered (Fig. 23).

The action of herringbone gearing is identical to that of single helical gearing, except that the thrust developed from the helix angle is self-contained within the shaft assembly, since the helix angle of the two tooth surfaces are opposite hand.

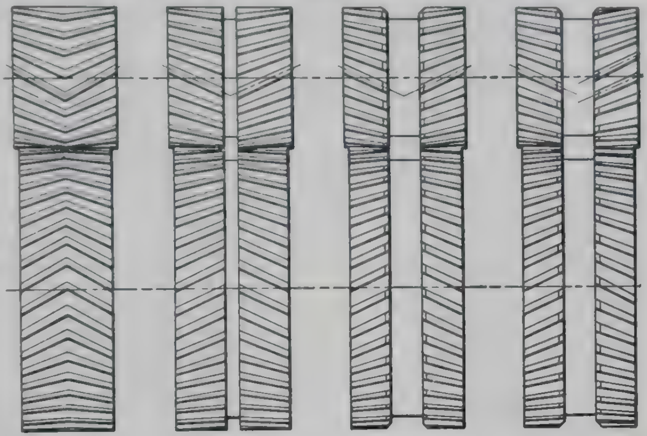


FIG. 23. Various types of herringbone gearing.

INTERNAL GEARING. An internal gear is one with the teeth cut into the bore instead of outside the rim, as is the case with a conventional spur or helical gear (Fig. 24). The internal gear possesses several advantages when properly applied and is frequently used for reduction gear and planetary gear combinations. In many respects, it can be treated as a conventional spur or helical gear. The same basic rack forms can be used, and the mating pinion is a conventional spur or helical gear. The center distance on an internal-gear drive is equal to the difference between the pitch radius of the internal gear and the pitch radius of the mating pinion. With an internal-gear drive, both members rotate in the same direction. With its shorter center distance the internal gear is more compact than the corresponding external-gear combination. Also, the tooth action is inherently smoother than that of a conventional spur or helical-gear drive. The tooth forms of the internal gear are stronger than those of the corresponding external toothed gears; they are stronger than the basic rack tooth form. For convenience in computing their beam strength, however, it is satisfactory to use the rack tooth form factor.

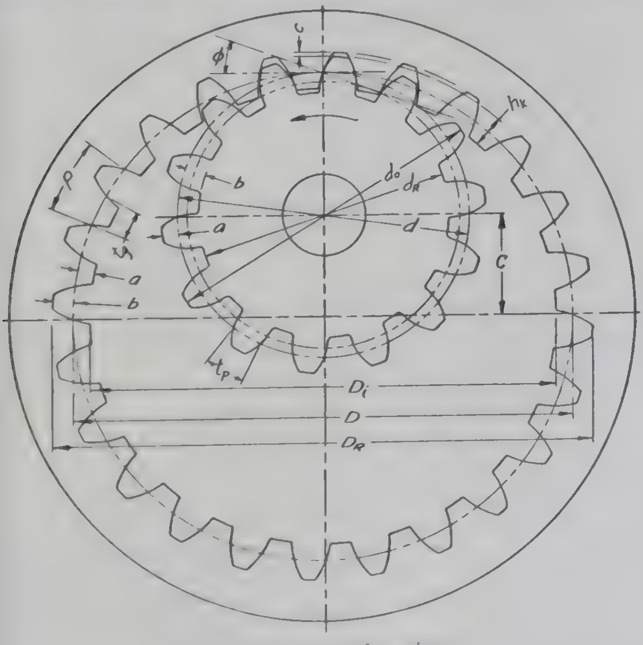

FIG. 24. Internal gearing.

When the internal-gear drive is used as a reduction drive, employing a small pinion and a large internal gear, the question of design as regards the tooth shape and action does not require special consideration. It is only when the number of teeth in the pinion closely approaches the number of teeth in the gear that it is necessary to lay out the teeth to see that proper tooth action is present without interference as the teeth come out of engagement. As a general rule, the smallest permissible difference between the number of teeth in the pinion and internal gear, to avoid this interference, is seven teeth for the stub-tooth form and twelve teeth for the full-depth tooth forms. Differences may sometimes be smaller, but this requires special design of tooth forms and proportions.

Internal gears may be cut with special formed milling cutters and an internal milling cutter attachment or they may be generated on a Fellows gear shaper or Sykes generator. Such generated gears may have straight or helical teeth. (See Ref. 12.)

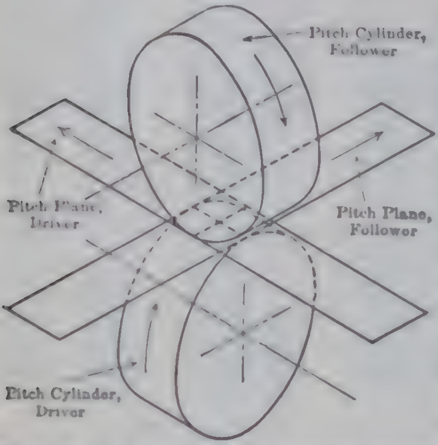

FIG. 25. Pitch surfaces of crossed-axis helical gears, pitch planes coinciding.

CROSSED-AXIS HELICAL GEARS, for light loads within their load-carrying capacity, are the most satisfactory type of screw gearing. When made with reasonable accuracy, they transmit motion smoothly and quietly, the result of several unique characteristics of such drives. Theoretically, it is impossible to spoil the nature of the action by mislocation or misalignment. As ordinarily designed, the pitch planes of mating gears coincide but travel in different directions (see Fig. 25), depending on the direction of the planes of rotation of the two helical gears. If the axes of the gears are moved farther apart, the sizes of the pitch cylinders will remain unchanged, the corresponding pitch planes will remain tangent to their respective pitch cylinders, and they will not coincide. (See Fig. 26.) The conjugate action between the tooth profiles, however, would remain theoretically correct. The gears could be designed so that the axes would be shifted to bring the entire tooth profiles between the two pitch planes, the only result being a relatively small reduction in the duration of contact.

A similar shifting of the pitch surfaces will occur if the angular setting of the axes of the gears is changed. The circular pitches on the pitch planes then would change, as these pitches depend on the direction of the plane of rotation of the mating gear in relation to their axial position, and this change would cause the size of the mating pitch cylinder to change accordingly. The results of these characteristics are that errors in the position or alignment of involute helical gears used on nonparallel shafts have no effect on the correctness of tooth action.

Generally, the helix angles on a pair of such gears are of the same hand. If the angle between shafts is small, however, the helix angles may be of opposite hand. Except when both helix angles are the same, there is no direct solution for the helix angles and pitch diameters of such gears, unless the center distance may be varied to suit the particular combination of helix angles which are selected arbitrarily. The final result in all other cases must be found by trial. When the two gears have helix angles of the same hand, the one with the greater helix, or lesser lead, angle should always be the driver. Except with gears of the same helix angle, the diameters of the gears are not directly proportional to the numbers of teeth. The speed ratio is established by the numbers of teeth and not by the diameters. Also the terms driver and follower are commonly used in place of the terms pinion and gear. Crossed-axis helical gears are sometimes known as spiral gears.

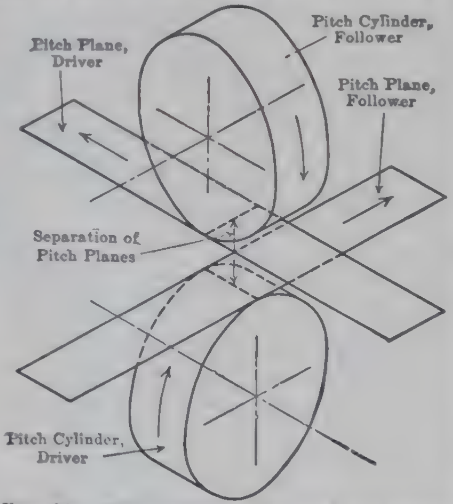

FIG. 26. Pitch surfaces of crossed-axis helical gears, pitch planes separated.

Let C = center distance, inches; P_n = normal diametral pitch (or diametral pitch of basic rack); n = number of teeth in driver; N = number of teeth in follower; α = helix angle of driver; β = helix angle of follower; γ = angle of axes; d = pitch diameter of driver, inches; D = pitch diameter of follower, inches. Then $d = n/P_n \cos \alpha$ and $D = N/P_n \cos \beta$.

When the two pitch planes coincide, $2C = d + D$.

When both helix angles are of the same hand, $\gamma = \alpha + \beta$.

When the helix angles are of opposite hand, γ = difference between α and β.

When L_1 = lead of driver, inches, and L_2 = lead of follower, inches, $L_1 = 3.1416d/\tan \alpha$, and $L_2 = 3.1416D/\tan \beta$.

The foregoing equations give all the basic relationships required to solve any spiral-gear problem. As noted before, in many cases the mathematical solution is indeterminate and must be solved by trial. The following simple graphical solution has been devised by J. K. Olsen, chief draftsman of the Stewart-Warner Speedometer Corporation.

Referring to Fig. 27, the number of teeth and the normal diametral pitch are selected arbitrarily. Circles are drawn representing the pitch diameters of the corresponding spur gears at the required center distance. Two intersecting straight lines are drawn on tracing paper, the angle between them corresponding to the angle between the shafts. This tracing is then placed over the two drawn circles and adjusted until both lines are tangent to their respective circles, their intersection being on the common center line of the two circles. The respective distances from the centers of the driver and follower to the intersection of the two lines on the common center line are the pitch radii of driver and follower. The angle between the vertical center line of each circle and the line tangent to that circle is the helix angle of that member. The values of the helix angle and the pitch radii would be measured from the layout, and should be checked by the foregoing equations. If the sum of the two pitch diameters so calculated is less than twice the specified center distance by not more than the depth of the tooth, no further refinement is necessary. The leads should be calculated from the formulas, using the measured values of the helix angles and the calculated values of the pitch diameters. The outside diameters of the gear blanks would then be chosen so that their sum equals twice the center distance plus twice the working depth of the tooth of the gear system used. The teeth would be cut to the standard depth in these blanks. The exact position of the tooth form in relation to the pitch cylinders is of little importance.

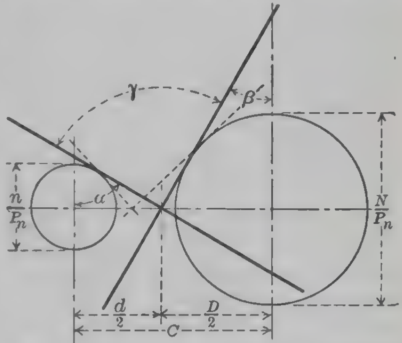

FIG. 27. Number of teeth in crossed-axis helical gears.

Figure 27 applies to the conditions when the two helix angles are of the same hand. In most cases, two points will be found on the common center line which meet the foregoing requirements. The point which gives the larger pitch radius and helix angle to the driver should be used. Sometimes the initial selection of tooth numbers and pitch results either in a condition where the intersection of the two lines on the tracing paper cannot touch the common center line, or the diameters so obtained are not satisfactory. In the first case, a new selection should be made which will reduce the size of the original circles. In the second case, a new selection should be made in which the size of the circles will be increased.

When the angle between the shafts is small, and the helix angles are to be of opposite hand, the procedure is as indicated in Fig. 28. The procedure is the same as before, except that one line must be tangent to one circle above the common center line, whereas the other line must be tangent to the second circle below the common center line.

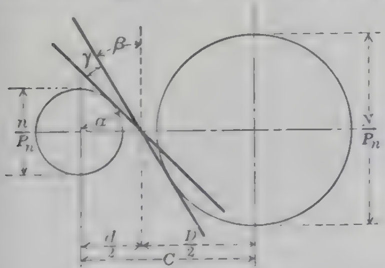

FIG. 28. Low shaft angle helical gears.

Tooth Forms for Spiral Gears. Either the 14 1/2-degree composite system for milled gears or the 14 1/2-degree full-depth involute system for generated gears gives the most satisfactory tooth forms for spiral-gear drives. The selection of the proper milling cutter, etc., for milled spiral gears is identical to that for helical gears as shown in Table 8.

Load-carrying Ability of Spiral Gears. The nature of the contact between spiral gears is point contact. Because of this point contact, relatively light tooth loads set up very high compressive stresses in the material at the point of contact. With spiral gears, excessive wear due to pitting or abrasion is usually the most critical condition to be avoided, as the teeth will wear excessively under much smaller loads than those required to break the teeth.

Practically no reliable information is available on the safe loads for wear on spiral gears. The limit load for wear on such gears is very uncertain. If the gears are operated in their actual working position under a light load for a period of time until a thin polished line or band appears on the teeth where contact occurs, they can carry appreciably greater loads without excessive wear than they could if assembled and operated under full load without the preliminary polishing run. Again, if the gears are carefully run in under increasing loads until a polished band of appreciable width appears on the surfaces of the gear teeth where contact takes place, they can carry very much higher loads without excessive wear than they can carry after only a short polishing run. In fact, the longer a pair of spiral gears runs without abrasive wear on the tooth surfaces, the greater will be the loads that they can carry without excessive wear. It should be apparent, therefore, that load factors given for spiral gears depend on the care with which they have been run in after their installation. With proper care, a load that would cause excessive wear on the gears when first assembled may often be increased to several times the original limit load, because of the influence of careful running in, without resulting in appreciable wear. On the other hand, when excessive abrasive wear has once started, it is almost impossible to stop it without shifting the position of the gears and thus bringing a new part of the tooth surface into contact.

The following formulas and load factors have proved to be reasonably reliable in practice. They are based on initial running in as indicated. The relationship of the dynamic load to the transmitted load is still an open question. In general, because of the screwing action of spiral-gear teeth, their operation is much smoother than that of spur or bevel gears. In the absence of definite information, the following relationship may be used. Let W = transmitted tooth load, pounds; W_d = dynamic tooth load, pounds; V = pitch line velocity of follower in plane of rotation, feet per minute; d = pitch diameter of driver, inches; D = pitch diameter of follower, inches; K = load factor, Table 9, and Q = ratio factor. Then

$$W_d = \left(\frac{1200 + V}{1200}\right) W; \qquad Q = \left(\frac{2 \times D}{d + D}\right)^2$$

$$W_w = d^2KQ$$

where W_w = limit load for wear in pounds.

Table 9. Values of *K* for Spiral Gears

Materials in Gears	After Short Polishing Run	After Careful Polishing Run
Steel and steel (250 Brinell)	2	5
Steel (250 Brinell) and bronze	4	12
Steel (500 Brinell) and bronze	5	20
Steel (500 Brinell) and cast iron	6	20
Steel (500 Brinell) and steel (500 Brinell)	7	15
Cast iron and cast iron	8	20
Nonmetallic and steel or cast iron	10	25

In general, to avoid sparking, bronze or nonmetallic materials or hardened steel should be used when the pitch-line velocity of either member in their plane of rotation is much in excess of 1000 ft per min. Bronze never should be used in combination with the nonmetallic materials for spiral gears because of the excessive abrasion or lapping that takes place on the bronze member.

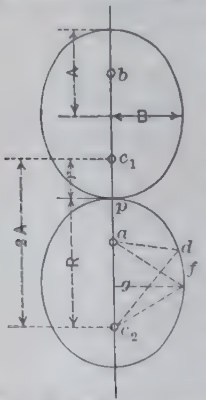

FIG. 29. Elliptical gearing.

ELLIPTICAL GEARS give a variable velocity ratio throughout the revolution. They represent a cheap way of obtaining a quick-return motion, and are so used on planers, shapers, slotters, and similar cutting tools, and also on pumps, shears, punches, and other machines which do their work mostly on the forward stroke of a reciprocating member. (See Refs. 2 and 3.) To determine the pitch ellipses for any given set of conditions, let c_1c_2 (Fig. 29) be the given distance between shaft centers. Divide c_1c_2 at p so that c_1p/pc_2 equals the extreme velocity ratio. Lay off $pa = pc_1$ for the other focus of the lower ellipse. As the ellipses must be equal, lay off $c_1b = c_2a$, and b is the other focus of the upper ellipse. The extremity f of the minor axis is found by making $af = fc_2 = {}^1/_2c_1c_2$. Any other point on the ellipse, such as d, is found by making $ad + dc_2 = c_1c_2$. The two free foci a and b remain at a constant distance apart during rotation, and are sometimes connected by a link. If $V = R^2 r^2$, A = one-half the major axis of the ellipse and B = one-half the minor axis, an equation which gives the ratio of the semimajor and semiminor axes for a given range of velocity ratio is

$$\frac{B}{A} = 2\sqrt[4]{V} \div (1 + \sqrt{V})$$

VARIABLE STANDARD CENTER DISTANCE GEARING. In some cases it is necessary to design gear trains to suit specific locations of driving and/or driven members. Often such requirements result in the center distance of a gear set varying from normal standard centers to such a degree that standard tooth proportions are not suitable.

The approach to this type of gear problem should preferably be made using full-depth generating types of cutters, although rotary cutters can be specially designed for each situation.

The best recommended practice is to increase (or decrease) the diameters of both mating members to suit the nonstandard center distance, the amount of increase or decrease for each being proportioned to the numbers of teeth. There are design limitation guides for this analysis, most important of which are given below.

For Increased Centers:

a. Check the number of teeth in contact at the maximum operating center distance and proportion addenda circles so as to obtain at least 1.1 teeth in contact.

b. Where extreme enlargement of the pinion teeth is required, a check should be made of the top land width so as to avoid a pointed condition or, in some cases, an insufficient cross section for heat treatment.

c. Sufficient running clearances, between outside diameter of each member and the root diameter of its mate, should be provided for minimum operating centers.

For Decreased Centers:

a. Undercutting should be avoided on the pinion teeth in order to maintain maximum strength characteristics.

b. Where undercutting of either gear or pinion cannot be avoided, contact conditions should be analyzed to avoid loss of continuous tooth action.

c. Where diameters must be reduced a substantial amount, the amount of material between the root diameter and the bore (or top of keyway or spline) should be checked.

5. BEVEL GEARING

TERMS AND DEFINITIONS. The terms *gear* and *pinion* when applied to bevel gears refer to the members with the larger and smaller number of teeth in the pair respectively. A *crown gear* has a pitch angle of 90 degrees. *Miter gears* have equal numbers of teeth and operate with axes at right angles. The angle between the axis of a bevel gear and an element of its pitch cone is called the *pitch angle.* Other terms applying to bevel gears are shown in Fig. 30. Note that the face-cone apex does not coincide with the pitch-cone apex. Instead the face cone of the blank is made parallel to the root cone of its mate, thereby giving constant clearance. This is preferred practice.

TYPES OF BEVEL GEARS. There are three types of bevel gears in general use.

Straight bevel gears have teeth which are straight and tapered and, if extended inward, would intersect at the axis.

Spiral bevel gears have curved oblique teeth on which contact begins gradually and continues smoothly from end to end.

Zerol bevel gears have curved teeth which are in the same general direction as straight teeth. They are spiral bevel gears with zero spiral angle.

There are also skew bevel gears having straight oblique teeth, but they are seldom used in the United States.

USES. The selection of the type of gear for a specific application is made according to operating requirements and mounting conditions.

Straight and **Zerol** bevel gears are satisfactory for peripheral speeds up to approximately 1000 ft per min where maximum smoothness and quietness are not of prime importance. In these applications plain bearings may be used, although antifriction bearings are always preferred.

Straight bevel gears, being the simplest to calculate and produce, are suitable for small lots where fixed charges must be kept to a minimum.

Zerol bevel gears are recommended in place of straight bevel gears (1) where hardened gears of extreme accuracy are required, since Zerol gears may have their teeth ground; (2) when the producer has only spiral-type equipment.

Fig. 30. Axial section of bevel gears showing terms.

Spiral bevel gears should always be used for speeds in excess of 1000 ft per min or 1000 rpm. In many instances they may be used to advantage at lower speeds, especially in applications where smoothness and quietness are important. Spiral bevel gears should, in general, be mounted on antifriction bearings because of the increased axial thrust of oblique teeth. Reference should be made to the manuals published by the bearing manufacturers to determine the loads and bearing sizes.

Cutter
Root line

Fig. 31. Root-line interference of bevel gear cutter.

Caution. In designing spiral bevel and Zerol bevel gears, all front and rear hub projections which extend above the root line must be eliminated. (See Fig. 31.)

STRAIGHT BEVEL GEARS (Fig. 32). Gears produced on the older bevel gear-cutting machines may have contact extending the full length of the tooth. Gears cut on the most recent machines have a localized tooth bearing and are called Coniflex gears. This localization permits slight misalignment in assembly and some displacement due to deflections under operating loads without causing the concentration of load on the ends of the teeth.

Table 13. Recommended Backlash

D.P.	Backlash
1.00 to 1.25	0.020-0.030
1.25 to 1.50	0.018-0.026
1.50 to 1.75	0.016-0.022
1.75 to 2.00	0.014-0.018
2.00 to 2.50	0.012-0.016
2.50 to 3.00	0.010-0.013
3.00 to 3.50	0.008-0.011
3.50 to 4.00	0.007-0.009
4 to 5	0.006-0.008
5 to 6	0.005-0.007
6 to 8	0.004-0.006
8 to 10	0.003-0.005
10 to 20	0.002-0.004
20 and finer	0.001-0.003

The table at left gives the recommended backlash for gears assembled ready to run. Because of manufacturing tolerances and changes resulting from heat treatment, it is frequently necessary to subtract more than half the recommended value from the theoretical tooth thickness of each member in order to obtain the correct backlash in assembly. In case of choice, use the smaller backlash tolerances.

Table 14. Typical Straight Bevel-gear Dimensions

(All linear dimensions in inches)

1. Number of pinion teeth	n (= 16)	5. Working depth h_k (Table 10)	(= 0.400)
2. Number of gear teeth	N (= 49)	6. Whole depth h_t (Table 10)	(= 0.440)
3. Diametral pitch	P (= 5)	7. Pressure angle ϕ	(= 20°)
4. Face width	F (= 1.5)		

	Pinion		Gear	
8. Pitch diameter	$d = \frac{n}{P}$	(= 3.2000)	$D = \frac{N}{P}$	(= 9.8000)
9. Cone distance	$A = \frac{D}{2 \sin \Gamma}$		(= 5.1546)	
10. Circular pitch	$p = \frac{3.1416}{P}$		(= 0.6283)	
11. Addendum	$a_P = h_k - a_G$	(= 0.284)	$a_G = \frac{\text{(Table 11)}}{P}$	(= 0.116)
12. Dedendum	$b_P = h_t - a_P$	(= 0.154)	$b_G = h_t - a_G$	(= 0.322)
13. Clearance	$c = h_t - h_k$		(= 0.038)	
14. Pitch angle	$\gamma = \tan^{-1} \frac{n}{N}$	(= 18° 5′)	$\Gamma = 90° - \gamma$	(= 71° 55′)
15. Dedendum angle	$\delta_P = \tan^{-1} \frac{b_P}{A}$	(= 1° 42′)	$\delta_G = \tan^{-1} \frac{b_G}{A}$	(= 3° 34′)
16. Face angle of blank	$\gamma_o = \gamma + \delta_G$	(= 21° 39′)	$\Gamma_o = \Gamma + \delta_P$	(= 73° 37′)
17. Root angle	$\gamma_R = \gamma - \delta_P$	(= 16° 23′)	$\Gamma_R = \Gamma - \delta_G$	(= 68° 21′)
18. Outside diameter	$d_o = d + 2a_P \cos \gamma$	(= 3.740)	$D_o = D + 2a_G \cos \Gamma$	(= 9.872)
19. Cone center to crown	$\frac{D}{2} - a_P \sin \gamma$	(= 4.812)	$\frac{d}{2} - a_G \sin \Gamma$	(= 1.490)
20. Circular thickness	$t = p - T$	(= 0.3703)	$T = \frac{p}{2} - (a_P - a_G) \tan \phi + \frac{K \text{ (Table 12)}}{P}$	(= 0.2580)
21. Backlash	(Table 13)		(= 0.005 to 0.007)	

NOTE. These remarks apply to the formulas in Table 14. *Item 4:* It is strongly recommended that the face width of bevel gears shall not exceed one-third the cone distance or $10/P$, whichever is smaller. In best design the ratio of face width to cone distance will be 0.25 to 0.30. Increasing the face width over recommended proportions results in manufacturing difficulties. *Item 7:* The pressure angle has been standardized at 20 degrees. *Item 12:* The dedendum value computed here is used in subsequent calculations. However, the actual dedendum will be greater by 0.002 in. *Item 20:* The circular thickness formula given here is for the theoretical value before deducting the allowance for backlash.

Angular Gears (Figs. 33 and 34). The formulas in Table 14 are not directly applicable for angular gears. Required changes are listed below by item number.

Item 14. Pitch Angles

Case 1. Shaft angle Σ is less than 90 degrees.

$$\tan \Gamma = \frac{\sin \Sigma}{\dfrac{n}{N} + \cos \Sigma}; \qquad \tan \gamma = \frac{\sin \Sigma}{\dfrac{N}{n} + \cos \Sigma}$$

$$\text{Check: } \Gamma + \gamma = \Sigma$$

Case 2. Shaft angle Σ is greater than 90 degrees, and Γ is less than 90 degrees.

$$\tan \Gamma = \frac{\sin (180° - \Sigma)}{\dfrac{n}{N} - \cos (180° - \Sigma)}; \qquad \tan \gamma = \frac{\sin (180° - \Sigma)}{\dfrac{N}{n} - \cos (180° - \Sigma)}$$

$$\text{Check: } \Gamma + \gamma = \Sigma$$

Case 3. Shaft angle Σ is greater than 90 degrees, and Γ is greater than 90 degrees (internal gear). In most cases this type of gear cannot be produced.

Item 11. Tooth Proportions

First compute equivalent 90-degree bevel-gear ratio:

$$\frac{N_{90}}{n_{90}} = \sqrt{\frac{N \cos \gamma}{n \cos \Gamma}} = \tan \Gamma_{90}$$

This value should be used as the ratio when determining the gear addendum for 1 DP in Table 11.

Item 19. Cone Center to Crown

$$\text{Pinion} = A \cos \gamma - a_P \sin \gamma$$

$$\text{Gear} = A \cos \Gamma - a_G \sin \Gamma$$

Item 20. Circular Thickness

To determine the value of K from Table 12, it is necessary to use equivalent 90-degree bevel-gear ratio given above (Item 11) and number of teeth in equivalent 90-degree bevel pinion:

$$\text{Equivalent } 90° \text{ ratio} = \tan \Gamma_{90}$$

$$n_{90} = \frac{n \sin \Gamma_{90}}{\cos \gamma}$$

Tooth Design for Bevel-gear Planers. Gears which are to be produced on a gear planer, where a former or template is used, should be designed with equal addendum teeth. Calculations for gear blanks which are to be cut by this method will be the same as given in Table 14, with the following exceptions:

Item 6: $$\text{Whole depth} = \frac{2.188}{P} \text{ in.}$$

Item 7: $$\text{Pressure angle} = 14\,{}^1/_2° \text{ or } 20°$$

Item 11: $$\text{Pinion addendum} = \text{gear addendum} = \frac{1.000}{P} \text{ in.}$$

Item 16: On planer-cut gears it has been customary to make the face-cone apex coincide with the pitch-cone apex. It is here recommended that the face cone of the blank be made parallel to the root cone of its mate. Accordingly, the formula given in Table 14 should be used.

Item 20: $$\text{Pinion circular thickness} = \text{gear circular thickness} = \frac{p}{2}$$

SPIRAL BEVEL GEARS. One of the principal features associated with spiral bevel gears is the complete control of the localized tooth contact. (See Fig. 35.) This localization permits some mounting deflection without concentrating the load dangerously near either end of the tooth.

Selection of Spiral Angle. Figure 36 shows how the spiral angle is measured. For best design practice, the spiral angle should be sufficient to give a face contact ratio of at least 1.25. The design chart (Fig. 37) may be used. The series of curves are for face contact ratios of 1.0 to 2.5. The spiral angle is plotted in terms of the product of face width and diametral pitch.

Tooth Design for Spiral Bevel Gears. Because the tooth proportions for spiral bevel gears are dependent upon the method of cutting, no formulas are included here. Where such information is desired, it is recommended that the application be discussed with a manufacturer of this type of gearing.

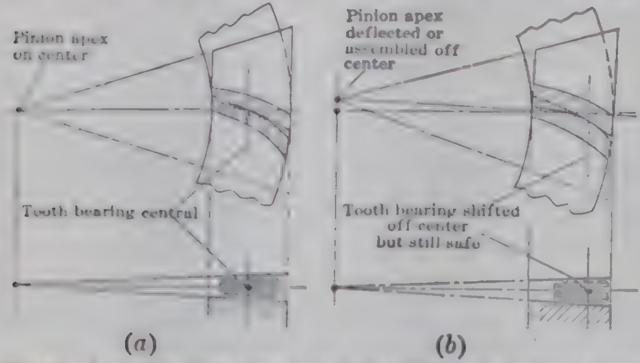

FIG. 35. Localized tooth bearing in spiral bevel gears, showing effect of displacement

ZEROL BEVEL GEARS can be manufactured on the same machines as are used for producing spiral bevel gears. All Zerol bevel gears are manufactured with a localized tooth contact. They have the same end thrust and tooth action as straight bevel gears, and may be used in the same mountings.

Tooth Design for Zerol Bevel Gears. Like spiral bevel gears, the tooth proportions depend on the cutting method. Problems involving this type of gear should be reviewed with a gear manufacturer for recommendations.

Hypoid Gears closely resemble spiral bevel gears but have the pinion axis offset from the gear axis. If there is sufficient offset, the shafts may pass one another, and, in general, a compact straddle mounting can be used on both the gear and pinion. Hypoid gears are usually designed so that the pinion has a larger spiral angle than the gear, making the hypoid pinion larger in diameter and, therefore, stronger than the corresponding spiral bevel pinion.

In general, the shaft offset should not exceed 40% of the equivalent bevel-gear cone distance, and on very heavily loaded gears, such as for truck and tractor axles, the offset should be limited to 20%.

The tooth surfaces of hypoid gears have some lengthwise sliding, the amount being a function of the offset. Hypoid gears are even smoother and quieter than spiral bevel gears, and for this reason are almost universally used in passenger automobile rear axles.

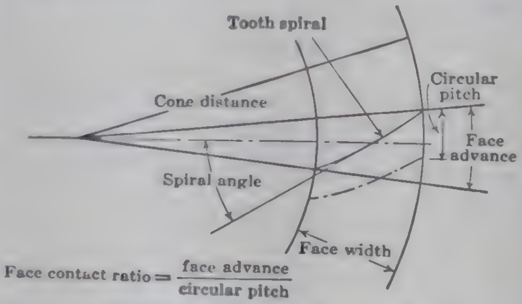

FIG. 36. Diagram defining spiral angle and face contact ratio.

These gears may be produced on spiral bevel gear machines having vertical adjustment of the work spindle.

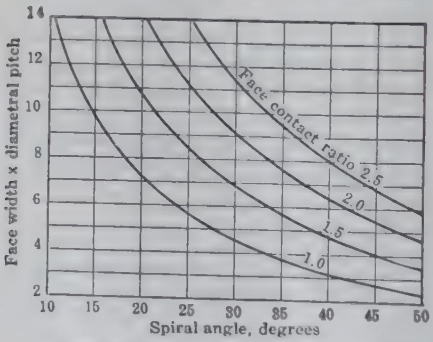

FIG. 37. Face contact ratio graph.

Tooth Design for Hypoid Gears. The tooth proportions for hypoid gears are related to the spiral angles and shaft offset. For this reason standardization has been impractical. Problems involving this type of gear should be reviewed with a gear manufacturer for recommendations.

GRINDING. Machinery is available for grinding the teeth of spiral bevel, Zerol bevel, and hypoid gears. The advantages of grinding are (1) increase in accuracy of hardened gears and (2) smooth blending of tooth profiles, fillets, and bottoms.

STRENGTH. For general industrial purposes, the beam strength of straight and spiral bevel gearing can be computed, using the following equation for peak strength rating from the AGMA standard rating practice:

$$P = \frac{snD_pFYC_v}{126{,}000C_BP_d}$$

where s = allowable bending stress = 250 times Brinell hardness number for untreated and heat-treated materials, or 300 times Bhn for case-hardened steels; n = pinion revolutions per minute; D_p = pinion pitch diameter, inches; F = face width, inches; Y = tooth form factor based on 1 DP with load at top of tooth (for spiral bevel gearing, use the tooth section in the transverse plane); C_v = velocity factor = $78/(78 + \sqrt{v})$; C_B = bevel gear factor = $A/(A - 0.5F)$, where A is the outside cone distance in inches; P_d = diametral pitch.

If the gearing is **critically loaded** or if the designer is interested in making a more detailed investigation of the stresses in bevel-gear teeth, the General Motors method of determining fatigue life should be referred to. Since this method involves considerable detail, those interested should review and analyze the complete method. Rather than an attempted briefing of the procedure, the following remarks are included to indicate only the theory.

It is a modification of the well-known Lewis formula arranged to determine the exact location of the point of application of the greatest load.

The general procedure is to determine the stress (following the detailed method developed by the Gleason Works) in the mean transverse section of the tooth when the total load is carried on one tooth in such a position that the tooth is under greatest stress. By means of layout and calculation, the stress in the weakest section is determined. (See Ref. 19.)

Comparing the calculated maximum stress with the General Motors stress-cycle graph establishes an estimated fatigue life. The General Motors data were established from records of life tests on hundreds of automotive spiral bevel gear sets; hence the extension of the life curve to industrial applications is accompanied by certain modifications of calculated values.

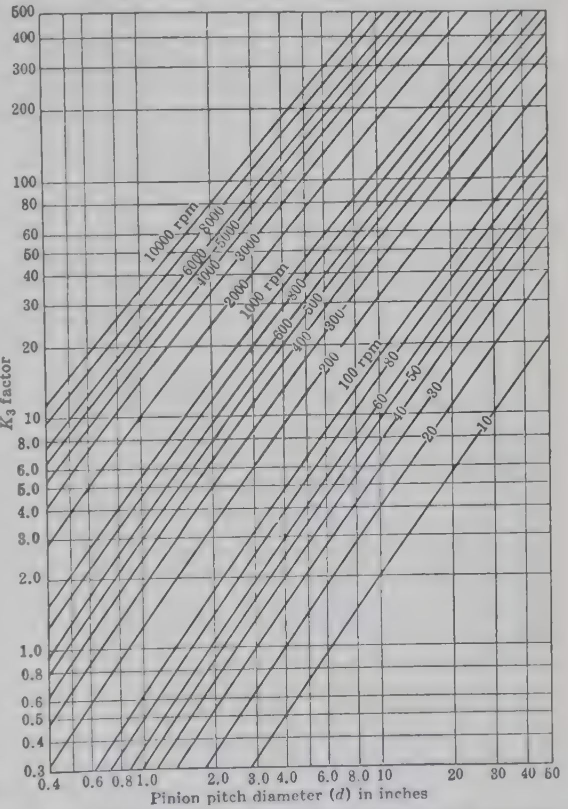

FIG. 38. Variation of K_3 factor with pinion pitch diameter.

Surface Durability. Except for cast-iron gears, surface-hardened gears, or gears of brittle material, surface durability is usually the determining factor for load capacity. The rating for surface durability is obtained from the following equation:

$$P = FC_MC_SK_3$$

where P = maximum continuous horsepower transmitted (instantaneous peak horsepower not to exceed twice this value); F = face width; C_M = material factor from Table 15; C_S = factor for contact ratio ($C_S = \sqrt{0.4m_F + m_p}$), where m_F = face contact ratio from the chart (Fig. 37), its value being zero for straight bevels and Zerol bevels; m_p = profile contact ratio, which is 1.2 for spiral bevels and 1.5 for straight bevels and Zerol bevels; and K_3 = combined factor for pinion diameter, velocity factor, revolutions per minute, and allowable unit load (Fig. 38).

MOUNTINGS. The proper design of shafts, bearings, and supporting structures is essential to successful gear performance. Rigid mountings should be provided; otherwise the gears will frequently fail prematurely.

The hand of spiral of a pair of spiral bevel gears should be selected carefully. In general, a left-hand spiral pinion driving clockwise (viewed from the back) or a right-hand pinion driving counterclockwise tends to move axially away from the cone center. If there is

Table 15. Material Factors for Bevel Gearing

* Minimum values.

excessive end play in the pinion shaft because of faulty assembly, the movement will introduce additional backlash. With the opposite hand of spiral, the pinion will move in and take up the backlash, and may even wedge.

Spiral bevel and hypoid gears should, in general, be mounted on antifriction bearings in an oiltight case. Both the gears and bearings should be locked against thrust in either direction, and the thrust bearings should be preloaded.

To provide proper support, the distance between bearings should never be less than 70% of the gear pitch diameter, and, on an overhung pinion, the distance should be at least 2½ times the overhang. The shaft diameter should be equal to or greater than the overhang in order to provide sufficient shaft stiffness.

LUBRICATION. The lubricating system should furnish a continuous supply of clean oil in sufficient quantity to lubricate and adequately cool the gears and bearings.

Splash lubrication is generally satisfactory for applications up to peripheral speeds of 2000 ft per min. The oil level should cover the full face of the lowest gear, and the quantity should be sufficient to maintain the oil temperature within recommended limits.

Pressure lubrication is used for velocities above 2000 ft per min. Spray lubrication is recommended with the jets located to direct the stream over the full length of the teeth on both members, preferably close to the mesh point on the leaving side. Jets should also be provided to lubricate the bearings. In general, oil temperatures should be kept near 150 F.

The "AGMA Specification on Lubrication of Enclosed and Open Gearing" is recommended as a guide to the type and grade of oil for various operating conditions.

EFFICIENCY. Various tests on bevel gears have shown efficiencies of over 99%. Accurately manufactured gears properly assembled in their mountings should easily show a gear efficiency of 98%.

Because of the lengthwise sliding encountered in hypoid gears, their efficiency will be slightly less than that of bevel gears. With the exception of high-ratio hypoids (over 10-to-1), efficiencies of 96 to 98% should be obtained.

6. LOAD-CARRYING CAPACITY OF GEARING

The ultimate in load-carrying abilities of gear teeth has so far been an elusive problem. The technological advancements in the art of producing tooth forms are improving the possibility of evaluating such factors as surface finish and load distribution on capacity determinations.

As of this writing, various experiments are being carried on to isolate and formulate many factors that are currently classed as "indeterminate" and, as a consequence, given an arbitrary value.

The load-carrying ability of gearing has been recognized for some time as contingent on contact conditions under load. As a consequence, in fields of high productions such as automotive and aircraft transmissions, complete assemblies are life-tested to provide "design constants" related to specific related conditions. Such values do not lend themselves to general use, and, as a consequence, there may appear to the uninitiated to be several "schools of thought" in the gearing field, whereas it will be found on closer inspection that the final design data in use stem from essentially the same basic considerations.

There are five principal elements to be dealt with in designing gear trains: first, resistance to breakage; second, resistance to surface wear (due to localized high unit stresses); third, resistance to scoring (due to high sliding velocities or a combination of high unit pressures and relatively high velocities); fourth, dynamic load conditions as they affect tooth-contacting conditions and/or the intensity of the imposed load; and, last, the indicated load-distribution characteristics of the mounting.

Several years ago someone said that "involute gears wear out—until they wear in—and then never wear out." Thus one observer recognized the effect of load-distribution qualities of the final setup of a gear train on its operating qualities, provided, however, that the gears were properly manufactured and given reasonable maintenance.

From a design viewpoint, then, it would appear necessary only to balance the strength, surface, contact, and deflection characteristics of a pair of mating gears to obtain a perfect solution to each power transmission problem.

The degree to which we analyze the various details connected with this phase of the design must be determined from the requirements of the mechanism. It is a sound conclusion that the best gear for a given application is the one that will satisfactorily perform all the functions for which it is intended, for the length of time specified and for the lowest possible cost of manufacture. So it is with capacity formulas. Where simple checks make it possible to proportion gear trains, they should be used. On the other hand, where the application demands that the most be made of available materials, the tooth proportions must be analyzed in great detail in order to achieve the maximum in load-carrying ability.

TOOTH-STRENGTH FORMULAS. The formula most generally referred to in strength calculations is a combination of the work of Wilfred Lewis and Carl G. Barth. The Lewis formula, presented in a paper read before the Engineers' Club of Philadelphia on October 15, 1892, was the first (see Ref. 1) to recognize the relationship of tooth form to gear-tooth strength. This formula is:

$$W = spfy$$

where W = transmitted tooth load, pounds; s = safe working stress of the material, pounds per square inch; p = circular pitch, inches; f = width of the gear-tooth face, inches; y = tooth-form factor, obtained by considering the gear tooth as a beam, fixed at one end and loaded at the other.

The y factor is generally established from a layout as shown in Fig. 39. In considering the gear tooth as a beam for the establishing of a tooth-form factor, the analogy and procedure may be summarized in the following way.

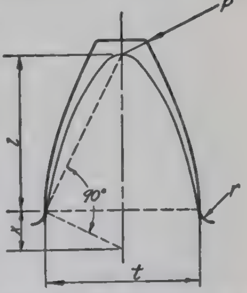

FIG. 39. Determination of y factor in Lewis equation.

The formula for the strength of a beam under comparable loading conditions (see Fig. 39) is

$$W = \frac{sft^2}{6l}$$

where W = load, pounds; s = maximum permissible fiber stress, pounds per square inch; f = width of beam, inches; t = thickness of beam (at critical section), inches; l = length of beam (from critical section to point of load application).

The layout shows that $x = t^2/4l$, and if this value is substituted in the beam equation, we have

$$W = sf\frac{2x}{3}$$

and for a gear tooth

$$W = Spf\frac{2x}{3p}$$

with the proportion $2x/3p$ becoming the y factor. The value of y for several gear-tooth systems is assembled for ready reference in Table 16.

The Barth contribution consisted of an approximation of safe working stresses in relation to pitch-line velocities in the form of the following equation:

$$S = \frac{600s}{600 + V}$$

in which S becomes the safe working stress, pounds per square inch; s is safe static stress, pounds per square inch (usually taken as one-third the elastic limit of the material); and V is pitch-line velocity, feet per minute.

It has since been recognized that the combination of the Lewis and Barth equations makes no allowance for the nature of the load, the influence of the amount of error in

gear-tooth action, and the influence of the rotating masses. Present-day usage of the Lewis formula includes variations of the basic formula, some of which are basically sound; others contain an arbitrary factor founded on experience. For instance, it is not uncommon to use varying velocity factors to represent varying degrees of gear-tooth action. Following are typical examples that have been used.

1. Limit the $600/(600 + V)$ factor to spur gears of commercial quality.
2. Use $900/(900 + V)$ for low-angle helicals or spur gearing where improved contact conditions justify.
3. Use $1200/(1200 + V)$ for high-angle helicals and herringbone gearing.
4. Use $78/(78 + \sqrt{v})$ for precision gearing.
5. Use $[150/(200 + V) + 0.25]$ for nonmetallic materials.

The influence of these modifications can be observed in the charted data of Fig. 40.

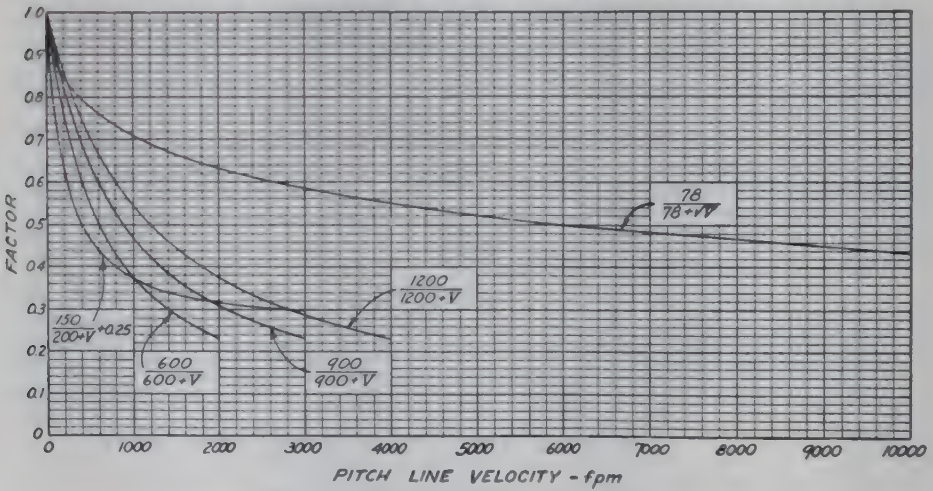

Fig. 40. Chart of velocity derating factors.

In addition to varying the velocity factor to suit the conditions, McMullen and Durkan (Ref. 22), in an analysis of the contact conditions in gear teeth, proposed a system of bevel gearing in which the point of application of the maximum load on the gear-tooth profile was used in arriving at strength ratings.

DYNAMIC-LOAD METHOD. In May 1926, Professor Earle Buckingham presented a spur-gear theory to the AGMA in which the load-carrying abilities of gear teeth were related to maximum specific compressive stresses from the Hertz equation

$$S^2 = \frac{0.35W\left(\frac{1}{R_1} + \frac{1}{R_2}\right)}{L\left(\frac{1}{E_1} + \frac{1}{E_2}\right)}$$

where W = load; R_1 and R_2 = radius of cylinder; E_1 and E_2 = modulus of elasticity of material; and L = length of cylinder. Also included was a method of evaluating the dynamic-loading condition based on errors of profile and pitch-line *velocity*.

The dynamic load is the maximum momentary load set up by the operating or dynamic conditions:

$$W_d = \frac{0.05V(FC + W)}{(0.05V + \sqrt{FC + W})} + W$$

where W_d = total dynamic tooth load, pounds; F = width of face, inches; and C = deformation constant from Table 17.

Table 17. Values of C *

Materials	Tooth Form	Error in Action of Gears, in. 0.0005	0.001	0.002	0.003	0.004	0.005
Cast iron and cast iron	14 1/2°	400	800	1600	2400	3200	4000
Cast iron and steel	14 1/2°	550	1100	2200	3300	4400	5500
Steel and steel	14 1/2°	800	1600	3200	4800	6400	8000
Cast iron and cast iron	20° full depth *	415	830	1660	2490	3320	4150
Cast iron and steel	20° full depth	570	1140	2280	3420	4560	5700
Steel and steel	20° full depth	830	1660	3320	4980	6640	8300
Cast iron and cast iron	20° stub	430	860	1720	2580	3440	4300
Cast iron and steel	20° stub	590	1180	2360	3540	4720	5900
Steel and steel	20° stub	860	1720	3440	5160	6880	8600

* The values given for cast iron also are used for bronze, since the modulus of elasticity is practically the same.

In order to use the foregoing formula, it is necessary to have some measure of the error in action of the gears. From tests of gears made in many plants, it appears that this error on well-cut industrial gears ranges from about 0.002 in. on gears of 6-diametral pitch and finer, to about 0.004 in. on gears of 2-diametral pitch. On gears cut with particular care, these errors are reduced by about one-half the above. On ground gears made with extreme care, and on cut gears where every effort is made to secure accuracy, these errors are reduced to even smaller amounts. The foregoing conditions of error are tabulated in Table 18 and classified as Class 1, Class 2, and Class 3, respectively.

Table 18. Maximum Error in Action between Gears

Diametral Pitch	Class 1	Class 2	Class 3
1	.0048 in.	.0024 in.	.0012 in.
2	.0040 in.	.0020 in.	.0010 in.
3	.0032 in.	.0016 in.	.0008 in.
4	.0026 in.	.0013 in.	.0007 in.
5	.0022 in.	.0011 in.	.0006 in.
6 and finer	.0020 in.	.0010 in.	.0005 in.

As a matter of fact, noise of operation is usually a very good test of the accuracy of gears. For example, gears to run at pitch-line velocities of 5000 ft per min and over cannot have errors much greater than about 0.0005 in., else the noise of operation will render them unsatisfactory. Table 19 gives some measure of the accuracy required at the different velocities. This table is a guide for the selection of the proper class of gear for specific speed conditions. For extreme quietness of operation, a higher order of accuracy than shown is necessary, even at the lower speeds. The values given should keep the noise of operation and the dynamic load within reasonable limits.

Table 19. Maximum Permissible Error in Action between Gears

Helical Gearing. As with all other types of gears, the load-carrying ability of helical gears may be limited by the heat of operation, the beam strength of the teeth, or the surface endurance limits of the materials. The dynamic load is the maximum momentary load set up by the operating or dynamic conditions. Where W = transmitted load at pitch line, pounds; V = pitch-line velocity, feet per minute; W_d = dynamic tooth load, pounds; F = width of active face, inches; C = deformation constant from Table 17; and α = helix angle of gears,

$$W_d = \frac{0.05V(W + FC\cos^2\alpha)\cos\alpha}{(0.05V + \sqrt{W + FC\cos^2\alpha})} + W$$

Helical and herringbone gears often are made with much wider faces than those commonly used on spur gears. With such wide-faced gears, the load across the face is not uniform because of the torsional deformation. The following approximation gives some measure of the intensity of this load concentration at one end of the face. When W_m = maximum unit dynamic load, pounds per inch of face, and D = pitch diameter of pinion, inches,

$$W_m = \frac{W_d}{F}\left(1 + \frac{F}{4D}\right)$$

For herringbone gears, the value of F in the above equation should be taken as the width of face of either half of the herringbone pinion because of the centering influence of the herringbone design. If the torsional deflection were uniform across the face, the load would vary uniformly across the face, the load being greatest where the torsional deflection is least. In such a case, the average unit load would exist at the middle of the face, with a maximum and minimum unit load at opposite ends, each varying the same amount from the average. This probably is a condition that never exists because the varying load will introduce a varying torsional deflection angle. For the sake of simplicity, the foregoing approximation is based on uniform torsional deflection across the face.

If W_w = limiting tooth load for wear, pounds (not to be less than the dynamic load for continuous service without appreciable wear); D = pitch diameter of pinion, inches; n = number of teeth in pinion; N = number of teeth in gear; α = pressure angle of gears; F = face width of gears, inches; Q = ratio factor; K = load-stress factor; E_1, E_2 = moduli of elasticity of materials; S_w = surface endurance limit of material, pounds per square inch,

$$Q = \frac{2N}{N + n} \quad \text{(for spur gears)}$$

$$Q = \frac{2N}{N - n} \quad \text{(for internal gears)}$$

$$K = \frac{S_w^2 \sin\alpha}{1.40}\left(\frac{1}{E_1} + \frac{1}{E_2}\right)$$

the Hertz equation becomes

$$W_w = DFKQ$$

The value of S_w for steel appears to vary quite consistently with its Brinell hardness numbers. Tests give, for steel, the values in Table 20.

Table 20. Values of S_w for Steel

Brinell Hardness No.	S_w	Brinell Hardness No.	S_w	Brinell Hardness No.	S_w	Brinell Hardness No.	S_w
150	50,000	300	110,000	450	170,000	550	210,000
200	70,000	350	130,000	500	190,000	600	230,000
250	90,000	400	150,000				

Table 21 gives values of K for various combinations of materials for 14 1/2-degree and 20-degree gears, taking into consideration the cold working received in operation. Some of the high-test semisteels and other special alloys of cast iron have a greater modulus of elasticity than cast iron, and the value of K for such materials must be calculated directly from their own specific properties.

Limit Load for Wear of Helical-gear Teeth. Let D = pitch diameter of pinion, inches; F = width of active face, inches; K = load-stress factor (same as for spur gears, Table 21); Q = ratio factor (same as for spur gears); α = helix angle; W_w = limiting load for wear, pounds. Then

$$W_w = \frac{DFKQ}{\cos^2\alpha}$$

The limiting load for wear should not be less than the dynamic load for continuous service without appreciable wear. The types of physical wear on helical gears are identical to those on spur gears.

In papers presented by Heymans and Kimball (Refs. 23 and 24) and by Timoshenko and Baud (Ref. 25), data were given from studies of gear-tooth stresses, using the photoelastic method of analysis. The results of studies clearly indicated the influence of the size of the fillet at the root of a gear tooth on the magnitude of the maximum stress developed in the tooth by the applied load. In evaluating stress concentration factors K, the ratio of the fillet radius r to the thickness of the tooth t_b at the base above the fillet is used. Figure 41 represents this relationship as currently used, based on photoelastic values arrived at in studies by Frocht.

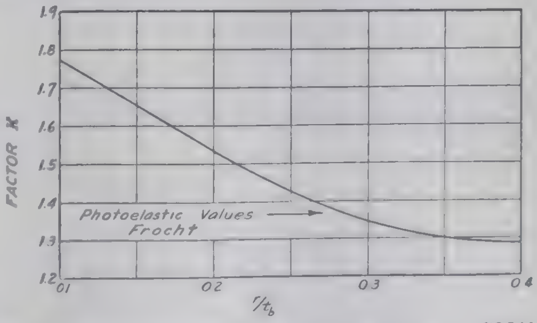

FIG. 41. Stress concentration factors for root fillet. (AGMA)

A paper by Frehse (Ref. 26) on automobile transmissions explores the method of computing stresses in helical gear teeth in which the effect of helix overlap on the contact conditions is recognized. J. O. Almen and Straub (Refs. 27 and 28) have given the gear industry relationships between computed stresses in automotive gearing and fatigue life (Fig. 42), data that have advanced the art materially.

Heldt (Ref. 4, p. 108) summarizes beam strength calculations in a similar manner, determining first the tooth carrying the maximum load (see Fig. 43) and then applying the beam strength formula as follows:

$$S = \frac{Fq}{u\,pz}$$

where S = stress in the weakest section; q = stress concentration factor for root fillet; u = face width, inches; p = circular pitch, inches; z = a tooth-form factor = $x/1.5p$ (Fig. 44); F = tangential tooth load at pitch line.

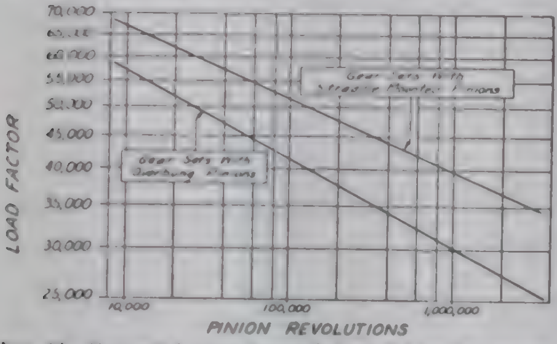

FIG. 42. Computed stress versus fatigue life for carburized spiral bevel gears. (Almen and Straub, *Automotive Industries*, Refs. 27, 28)

WEAR RATING METHODS. As speeds of gearing have increased, and methods of producing gear tooth forms have improved, it has become more and more apparent that more gears fail because of wear or surface destruction than by breakage. A review of established practice reveals many industries in which satisfactory gear performance was correlated to a load per inch of face per inch of diameter without reference to tooth proportion. Obviously, the gear teeth were checked for strength, but the loading factor widely known as the K factor was imposed as an overall limit.

Among the experimenters who have worked to establish optimum values for wear is S. Way of the Westinghouse Research Laboratories, who has made studies of the so-called pitting limit of gear teeth. In Ref. 29 and in an article appearing in the April 1936 issue of *The Electric Journal*, it was shown that the subsurface shear theory, using the Hertz method of computing stresses, resulted in relating maximum allowable compressive stresses to Brinell hardness. The exact relationship depends greatly on surface finish so that it appears unwise to include an index at this time. In the AGMA rating practices, the durability ratings for wear are based on an assumed endurance limit curve related to experience using the formula

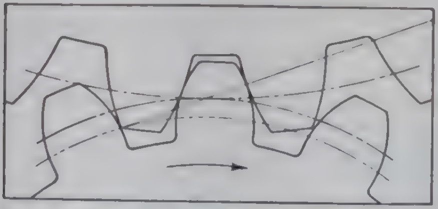

FIG. 43. Diagram showing highest point on flank at which one tooth carries the load. (Heldt, *Torque Converters and Transmissions*, Ref. 4)

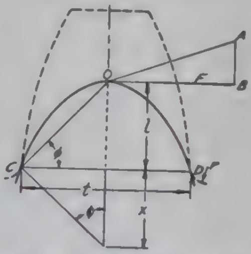

FIG. 44. Tooth-form factor z equals $x/1.5p$. (Heldt, *op. cit.*)

$$S_s = 958\sqrt{\frac{P(R_1 + R_2)}{2R_1R_2}}$$

which is the equation for the magnitude of the maximum shear stress in steel cylinders (where Poisson's ratio = 0.25) occurring at a distance equal to 0.393 times the width of the flattened area arrived at in the Hertz formula. Arbitrary combinations of hardnesses between mating members are used to provide for the difference in number of stress cycles in the two members.

F. R. McFarland (Ref. 30), has outlined analyses made on aircraft engine gears in which surface stresses computed by the Hertz method and sliding velocities were correlated (Fig. 45) on Almen's PV basis to explain operating performance. In these studies

$$P = \frac{0.35 \times \text{tooth load} \times \left(\frac{1}{R_1} + \frac{1}{R_2}\right)}{\text{Face width} \times \left(\frac{1}{E_1} + \frac{1}{E_2}\right)}$$

V = instantaneous tangential velocities (see Fig. 46)

$$PV = P \times (V_2 - V_1) = \frac{\text{lb}}{\text{in.}^2} \times \frac{\text{ft}}{\text{sec}}$$

Heldt (Ref. 4), dealing principally with automotive transmission gearing, applies the compressive stress method of evaluating load-carrying abilities of surfaces of gear teeth and comments on the relationship between surface loading and rubbing speed. His formula for gear teeth is:

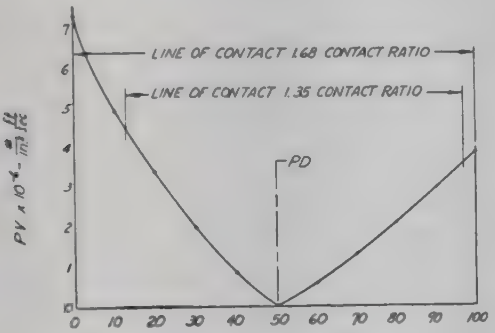

FIG. 45. Typical *PV* chart for gear teeth. (McFarland, *SAE Journal*, Ref. 30)

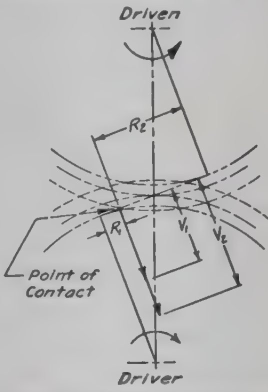

FIG. 46. Instantaneous sliding velocities at point of contact. (McFarland, *op. cit.*)

$$S_c = \sqrt{\frac{PE(p+1)}{3.5fR \sin 2\phi}}$$

where P = tangential load at pitch line, E = modulus, p = gear ratio, R = pitch radius of larger gear, and ϕ = pressure angle.

Values of S_c used in automotive practice in which allowance is made for dynamic loading are:

Case-hardened 3 1/2 % nickel steel	200,000 psi
Oil-hardened SAE 2350 and 3250	160,000 psi
Case-hardened SAE 4615 and 2315	200,000 psi
Case-hardened SAE 4815 and 2512	220,000 psi

Where the service conditions require operating under continuous loads, it is recommended that the limiting compressive stress values be reduced approximately 25%.

AGMA PROCEDURES—Strength Rating. The AGMA has adopted standard rating practices for various types of gears. Methods are given for beam-strength calculations and surface durability that have been related to the accumulated experience of its members. These data are:

1. "Strength of Spur Gear Teeth"—AGMA Standard 220.01.

$$P = \frac{sF_iY_kD_G}{P_d}$$

2. "Strength of Helical and Herringbone Gear Teeth"—AGMA Standard 221.01.

$$P = SY_{hk}FZM_nD_m$$

3. "Beam Strength of Straight Bevel and Spiral Bevel Gear Teeth"—AGMA Standard 222.01.

$$P = \frac{snD_pFYC_v}{126{,}000C_BP_d}$$

In the foregoing strength-rating practices, the symbols used refer to the following:

P = peak horsepower rating for strength
s = allowable bending stress (see Table 22)
F_i = face-width factor (see chart, Fig. 47)

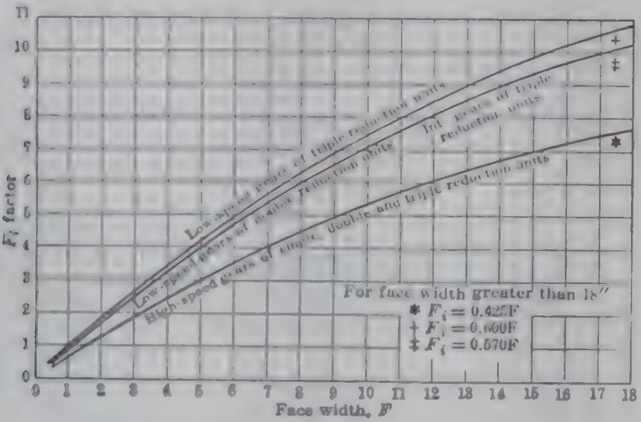

FIG. 47. Chart for face-width factor, F_i. (AGMA)

Y_k = tooth-form factor for spur gearing calculated from the following formula and Fig. 48:

$$Y_k = \frac{1}{K_c \dfrac{\cos \phi_L}{\cos \phi}\left(\dfrac{1.5}{X} - \dfrac{\tan \phi_L}{t}\right)}$$

335 Bhn steel	77,000 psi
360 Bhn steel	83,000 psi
440 Bhn steel and higher	90,000 psi

Wear Rating. For surface durability (wear rating), the AGMA data available are:

1. "Surface Durability of Spur Gears"—AGMA Standard 210.01.

$$P = F_i K_r D_o C_f$$

for 20° stub or 20° full-depth teeth. Where 14 1/2° full-depth teeth, a 0.75 multiplier is used.

2. "Surface Durability of Helical and Herringbone Gears"—AGMA Standard 211.01.

$$P = F_i K_r D_s$$

3. "Surface Durability of Straight Bevel and Spiral Bevel Gears"—AGMA Standard 212.01.

$$P = C_{mb} D_b F$$

In the foregoing formulas, the symbols used refer to the following:

P = allowable horsepower rating for service duty involving uniform loads and not over eight hours a day

F_i = face-width factor for spur, helical, and herringbone gears (see Fig. 47)

K_c = combined factor for spur, helical, and herringbone gearing covering material tooth-contact relationship and ratio factors (see charts, Figs. 50 and 51)

FIG. 51. Factor K_{ri} for internal gearing. (AGMA)

D_o = diameter and speed factor for spur gearing from the formula $D_o = \dfrac{D_p^2 C_{vs} n}{158{,}000}$

C_f = modification factor for increased stress in spur gearing at the point where single tooth contact occurs. Tables for this value are supplied in AGMA data; however,

$C_f = \dfrac{\rho_G \rho_p}{r_G r_p}$, where

ρ = radius of curvature at start of single tooth action and r = radius of curvature at the pitch point

D_s = diameter and speed factor for helical and herringbone gearing from

$$D_s = \frac{D_p^2 C_v n}{126{,}000}, \text{ where } C_v = \frac{78}{78 + \sqrt{v}}$$

C_{mp} = materials factor for bevel gearing (see Table 15).

D_b = diameter and speed factor for bevel gearing, from

$$D_b = \sqrt{\frac{D_p D_{pm} C_v}{233}}$$

7. PROPORTIONS OF GEAR BLANKS

Gear blanks vary widely in their construction, depending largely on end use, mounting arrangement, type of material, and overall economy. There are no "standard rules" governing the proportioning of gears; however, "good practice" has established desirable relationships between pitch and face width, also maximum diameters for given face widths. The following notes should guide the designer into good overall proportions for general-purpose gearing.

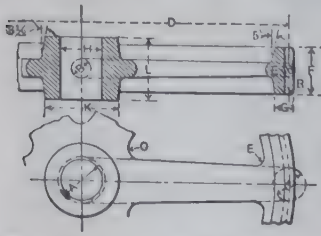

FIG. 52. Machine tool gear blank proportions.

MACHINE TOOL GEARING (Brown & Sharpe Manufacturing Co., Providence). A regular system of proportioning gears must be followed, if the gears are to have good proportions, sufficient strength without excessive weight, and uniform appearance when the gears are used in sets. The following formulas and Table 23 refer to Fig. 52, and are for gears of 4 in. diameter, 20 diametral pitch, to 72 in. diameter, 1 1/2 diametral pitch. D = pitch diameter, P = diametral pitch, d = dedendum, f = addendum, and t = thickness of tooth at pitch line. The significance of the other factors in the formulas is shown in Fig. 52.

Table 23. Formulas for Proportions of Spur Gears

Proportions of Arm

$A = 0.138D\,[(0.95/P) + 0.28] + 0.67$
$a = 2/3\ A$
$B = 0.4A$
$b = 0.4a$ or $2/3\ B$
$C = 1/4\ A$

Proportions of Hub *

$K = 1.5H + 1/4$ in.† $L = 1.5H$

Proportions of Rim

$^*F = (8/P) + 0.25$
$E = 1/4\ A$
$G = (d + f) + t + 0.06$
$R = 1/32$ in. (to 20 pitch incl.)
$3/64$ in. (to 14 pitch incl.)
$1/16$ in. (to 8 pitch incl.)
$3/32$ in. (to 4 pitch incl.)
$1/8$ in. (above 4 pitch)

Values of $(0.95/P) + 0.28$ for Finding A

Diametral pitch	1	1 1/2	2	2 1/2	3	4	5	6	7	8	9
$(0.95/P) + 0.28$	1.23	0.915	0.755	0.660	0.597	0.520	0.470	0.44	0.42	0.40	0.39
Diametral pitch	10	11	12	13	14	15	16	17	18	19	20
$(0.95/P) + 0.28$	0.38	0.37	0.36	0.354	0.352	0.345	0.340	0.337	0.334	0.332	0.33

* Suitable for general practice. For light change gears, F should be less than given by formula. The hole H should vary to suit conditions, but can usually be made to agree with one of the following formulas:

$$H = \frac{4}{P} + 0.5; \qquad = \frac{5}{P} + 0.5; \qquad = \frac{6}{P} + 0.5$$

† Where heavy service is required, or large set screws or keyways are to be used, make $K = 1.625H + 1/4$ or reinforce hub over keyway or around set screw.

TO DETERMINE WHETHER GEARS SHALL BE SOLID, WEB, OR ARM. Gears to be used together should be consistent as to construction. Table 24 shows the maximum diameter that should be used in each style of gear. Diameters greater than those shown in the "web" column should be made with six arms, of the proportions given by the formula above.

Table 24. Maximum Permissible Diameter of Solid and Web Gears

Diametral Pitch	Solid Gears		Web Gears		Diametral Pitch	Solid Gears		Web Gears	
	Change, in.	Combination, in.	Change, in.	Combination, in.		Change, in.	Combination, in.	Change, in.	Combination, in.
4	5.50	6.00	9.00	9.50	10	3.80	3.80	5.80	6.00
5	4.80	5.00	7.50	8.00	12	3.67	3.67	5.67	5.75
6	4.50	4.75	7.30	7.75	14	3.29	3.29	5.30	5.50
7	4.30	4.57	6.86	7.00	16	3.13	....	4.15	....
8	4.25	4.25	6.75	6.88	18	3.00	....	4.55	....
9	4.00	4.00	6.67	6.75	20	2.80	....	4.40	....

For ordinary service, "combination" gears should be used, the "change" gears being adapted only for light service.

ARM STYLES AND PROPORTIONS FOR GENERAL-PURPOSE GEARING. Suitable proportions of sections for gear wheel arms are shown in Fig. 53 (see also Ref. 5). It is also suggested that the section modulus of the arm at the center of the hub be computed for the formula $I/c = WR/nS$, where W = load on the gear; R = length of arm, or radius of the gear, inches; S = allowable fiber stress of the material; n = number of arms in the gear; I = moment of inertia of section; and c = distance of extreme fiber from axis. This formula for the elliptical section gives

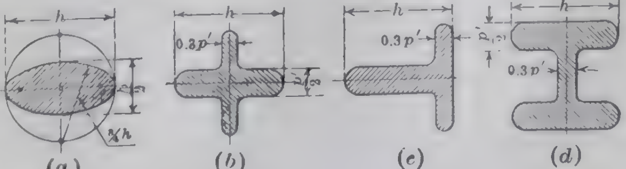

Fig. 53. General-purpose gear blank arms.

$$\frac{I}{c} = h\sqrt[3]{\frac{20WR}{nS}}$$

The dimensions of the arm at the pitch line can be approximately 0.7 of those at the center.

The number of arms suggested are: for gears up to 16 to 20 in. diameter, 4 or 5 arms; for gears 20 to 60 in. diameter, 6 arms; for gears 60 to 96 in. diameter, 8 arms; for gears over 96 in. diameter, 10 or 12 arms. For small gears, web centers of thickness approximately one-half the circular pitch are recommended.

H-ARMS FOR HEAVY-DUTY GEARING. The axial thrust loads in helical gearing and the heavier loads imposed by heavy-duty service have increased the popularity of the H-arm to the point where additional guidance on its proportions is outlined herewith.

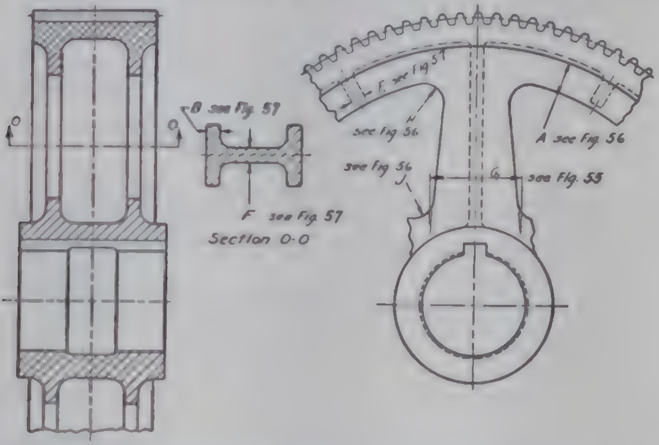

FIG. 54. Typical H-arm blank for heavy-duty gearing.

Figure 54 shows a typical H-arm gear blank design in which the proportions are based on the following assumptions:

Maximum Face Widths

6, 5 and 4 DP	10 in.
3 1/2 and 3 DP	12 in.
2 1/2 and 2 DP	15 in.
1 3/4 and 1 1/2 DP	18 in.
1 1/4 and 1 DP	21 in.

Number of Arms

Up to 30 in. diameter	4 arms
31 to 45 in. diameter	5 arms
46 to 120 in. diameter	6 arms

Hub diameter in relation to the bore varying in relation to bore size and pitch of teeth (index of capacity) from 1.7 to 1 for heavy pitches, and 1.5 to 1 for lighter pitches.

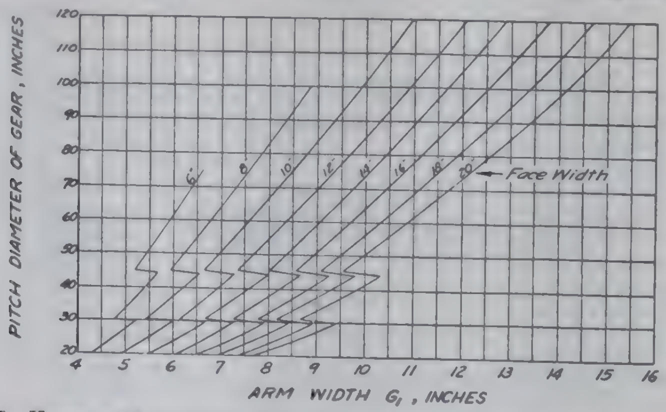

FIG. 55. H-arm width proportions for heavy-duty gearing. See dimension G_1, Fig. 54.

Hubs of blanks counterbored wherever possible for approximately one-third the hub length and a depth of 1/32 in. for bores up to 12 in., and 1/16 in. above. As a guide, counterbores should be provided where the hub length is greater than two times bore diameter up to 5 in. bore size; or 1 1/2 times bore diameter in bore sizes 5 in. to 14 in.; and in all bore sizes above 14 in. diameter.

Arm width proportions—Fig. 55

Flange depth—Fig. 56

Web thickness—Fig. 57

Rim thickness under the tooth equal to the whole depth of full-depth teeth of the pitch involved.

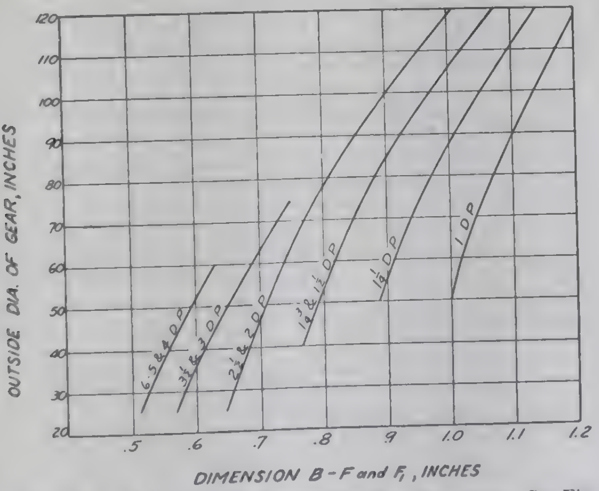

FIG. 57. Web thicknesses for heavy-duty H-arm gearing. See Fig. 54.

8. WORM GEARING

A common conception of a worm-gear drive is a screw thread driving a circular nut. A better mental image is obtained by picturing such a drive as the development of a spiral-gear drive where one member has been made to envelop the other in order to obtain line contact instead of point contact. Either member may be made to envelop the other. For expediency, the more common practice has been to make the larger member envelop the smaller. Until recently, the use of a smaller member enveloping the larger one has been exceptional, and such a construction has been erroneously called an hourglass or globoid worm drive. A worm-gear drive has one member with a uniform helical lead of tooth along its axis, while the mating member is made to envelop it. The enveloping member retains its cylindrical pitch surface, but loses its pitch plane with the loss of its uniform helical lead of tooth along its axis. The helicoidal member retains its pitch plane but loses its pitch cylinder because the mating pitch plane has been eliminated. Thus the pitch surfaces of a worm drive consist of a pitch cylinder on the enveloping member and a pitch plane on the helicoidal member, and there is but one common circular pitch for both members. There can be no circular pitch in the plane of rotation of the helicoidal member unless there is a mating pitch plane with a constant axial pitch on the contacting member. The contact between the teeth of a worm-gear drive is line contact.

CONVENTIONAL WORM-GEAR DRIVES. In general, worm drives are used to drive shafts at 90 degrees to each other. They can be substituted, however, for any crossed-axis helical gear drive, regardless of the angle between the shafts.

Pitch surfaces consist of a pitch plane on the helicoidal member and a pitch cylinder on the enveloping member. The conjugate tooth action can best be studied as a special case of a rack and a gear. The same conjugate tooth action exists when the helicoidal member is moved, without revolving in an axial direction, as exists when the helicoidal member revolves. The rack form, however, is not constant across the face of the enveloping member, but is of changing form. (See Fig. 58.) The amount of change in form depends upon the thread angle in the axial section, the lead of the helicoid and its diameter, and the distance of the particular section from the axial plane.

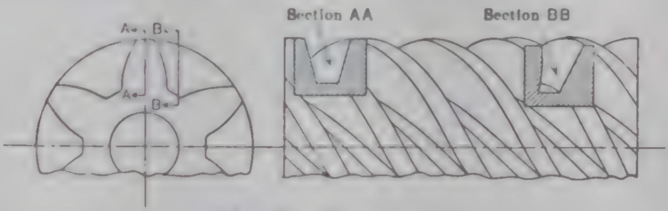

Fig. 58. Worm gear.

Lead and Thread Angles. Because of these conditions, higher thread angles are required for effective tooth action as the lead angle is increased. Narrower faces for the enveloping member are sometimes desirable for the higher lead angles, particularly if the thread angle in the axial section is relatively small. Thus a 14½-degree thread angle should not be used for lead angles greater than about 15 degrees; a 20-degree thread angle should not be used for lead angles greater than about 25 degrees; a 25-degree thread angle should not be used for lead angles greater than about 35 degrees; and a 30-degree thread angle is desirable for lead angles up to 45 degrees.

Profile Variations. Many types of helicoids are used for worms. Where the lead angle is small, the actual forms produced by different methods of cutting the thread are similar, although they are different types of helicoids. As the lead angles increase, however, marked differences become apparent. For example, the axial form of the thread profile produced by a straight-sided lathe tool, tipped to the lead angle, is concave. That produced by a straight-sided milling cutter set to the lead angle generally is convex; although in extreme cases where the diameter of the cutter is small in relation to the depth of the thread and the lead angle is large, the axial form may be of double curvature, convex near the root and concave near the outside or tip of the thread. The larger the diameter of the cutter, the greater the amount of curvature in the axial profile of the thread, because of the side-cutting action of the cutter. If the milling cutter axis is parallel to the axis of the helicoid or worm, a condition that exists when hobbing a thread with an annular cutter, the form produced is that of an involute helicoid which is that of an involute helical gear. This same involute helicoid also is produced when the flat side of a cutter or grinding wheel, set to both the thread angle and lead angle, is used. Figure 59 shows the differences in axial profile produced on a worm with a lead angle of nearly 45 degrees by different tools of the same form of cutting edge. These tools include a straight-sided threading tool set to the lead angle, a 4-in. diameter milling cutter, a 12-in. diameter grinding wheel, and the involute helicoid which would be produced by the flat side of a milling cutter or grinding wheel.

All these forms of helicoids have been commonly used as thread forms for worms. As far as theoretical conditions are concerned, one type does not appear to have any great inherent advantage over another. The major consideration is that the form of helicoid used for the worm should be reproduced on the cutting tool which is to be used to generate the enveloping member. In general, the best form to use is largely a matter of expediency, controlled by the type of equipment available to produce the helicoidal member. Hence the toolmaker must know the method to be used to produce the helicoidal member in order to make correctly the cutting tool which is to be used to generate the enveloping member.

Involute Helicoid. For many practical reasons, the involute helicoid would appear to be the best form to use where the design is not restricted by existing equipment. With this helicoid, the same hob or generating cutter which is used to generate the enveloping member also may be used to generate the worm or helicoidal member. Again, with this helicoid, the helicoidal members would be involute helical gears, and the same hob or other generating cutter could be used to generate all worms of the same normal diametral pitch of all tooth numbers. Under such conditions, the practice and technique already developed in the making of tools for helical and spur gears could be applied directly to the making of tools for worms and worm gears. Furthermore, this involute helicoidal form, where ground worms are required, is the simplest one to grind and control; the size of the wheel has no influence on the form produced; and several different grinding methods are available.

Fig. 59. Axial sections of milled and chased worms.

In further discussion, the angle of the thread form will refer to the tangent to the thread profile at or near the middle of the working depth, regardless of the type of helicoid involved.

CONTACT ON WORM-GEAR DRIVES. The analysis of worm drives is a very complex operation. In the majority of cases where such analyses have been made, only the conjugate action between parallel sections of the worm, treating them as rack sections meshing with the enveloping member or gear, has been considered. In addition, it is necessary to have some measure of the nature and position of the actual contact lines between mating teeth, duration and field of contact between them, in order to determine even approximately the intensity of the stresses and probable load-carrying capacities of such drives. Fortunately all types of helicoids follow certain general laws so that workable approximations are possible in all except the extremely critical conditions.

Projection of Field of Contact

Fig. 60. Contact lines in worm gearing.

Considerable uncertainty exists as to the most effective position of the pitch plane in relation to the tooth on the worm. The conventional design places it at the middle of the working depth of the tooth or thread on the worm. The practice in some plants is to place it nearer the root of the thread. On all types of helicoids, the tendency of the contact lines is to converge toward the pitch line on the leaving side of the worm. (See Fig. 60.)

This shows a six-thread worm with straight sides of thread in an axial section, meshing with a forty-tooth gear. The heavy outline on the plan view of the worm shows the projection of the field of contact. In the relative position of the two members as shown, contact exists on three threads of the worm as shown by heavy lines *A*, *B*, and *C*.

With this same worm, when the pitch line is dropped to the outside diameter of the gear, by simply closing in the center distance the amount that the pitch plane is moved, the contact conditions are as shown in Fig. 61. Here the contact lines tend more to sweep from the bottom to the top of the worm thread. This change in position of the contact lines causes much lower stresses to be set up in the materials by the same applied load, as compared with the conditions in Fig. 60. Because of the relative curvature conditions at the contact lines the drive (Fig. 61) can safely carry about double the loads that the drive (Fig. 60) can carry, even with a portion of the gear face undercut as shown. With lower lead angles, the change is less with a change in the position of the pitch plane.

FIG. 61. Contact lines and field of contact with pitch line moved to outside diameter of gear.

In the design of a worm drive, the center distance can be varied a limited amount, and the pitch plane may be placed anywhere between the middle of the working depth of the thread on the worm and the outside diameter of the gear to suit other conditions, such as a prefixed center distance. On the other hand, the lower the pitch plane is placed on the worm thread, the greater will be its load-carrying capacity and the smoother the action.

DESIGN OF WORMS. There is considerable difference of opinion as to whether the form of the thread in the axial section or that in the so-called "normal section" should be specified. As a matter of fact, there is no "normal section" as generally implied on any helicoid. As noted before, the essential information is best specified by stating the shape, type, and size of the tool to be used to finish the worm. The AGMA recommends that the thread form to be regarded as standard will be the form produced by a straight-sided milling cutter having a diameter not less than the outside diameter, nor greater than 1 $^1/_4$ times the outside diameter, of the worm; also, that the following linear pitches be regarded as standard: $^1/_4$, $^5/_{16}$, $^3/_8$, $^1/_2$, $^5/_8$, $^3/_4$, 1, 1 $^1/_4$, 1 $^1/_2$, 1 $^3/_4$, and 2 in.

Since the pitch surface of the worm or helicoidal member is a plane, and since the pitch on such a plane is constant at all distances from the axis, the term "pitch diameter of a worm" is misleading. Considering it as on a screw thread, where the same term is used to define that diameter where the thread thickness is equal to the width of space, or where both distances are equal to one-half the pitch, it might best be called the nominal pitch diameter or, better, the effective diameter.

The AGMA also recommends that the top edge of the worm thread should always be rounded to avoid cutting, and that the amount of this rounding be made equivalent to 0.05 linear pitch. When the pitch plane of the worm is dropped to about its root diameter or lower, and the worm is the driving member, the conjugate tooth action at this edge always is recess action, and under such conditions this rounding is not necessary.

The AGMA recommends the use of a 14 $^1/_2$-degree and a 20-degree thread angle for worms from single to quadruple threads. As noted before, the lead angle and not the number of threads is the major factor that should determine the selection of the thread angle. To these two angles could be added a 25-degree and a 30-degree thread angle to cover all lead angles up to 45 degrees or higher. If a single thread angle is to be used, the 30-degree thread angle can be effectively used on the lower lead angles, and several manufacturers of worm gears have adopted this angle as standard for all worms, with very satisfactory results.

MILLED AND CHASED WORMS. For milled and chased worms, where definite axial pitches are maintained, a choice between two procedures is necessary. (1) If fixed tooth heights are used for the same pitch, regardless of the lead angle, a different cutter will be required for each different lead angle. (2) If the same milling cutter or chasing tool is to be used for all worms of the same axial pitch, regardless of the lead angle, a different tooth height must be calculated for each lead angle. In general, as regards the standardization of gears, greatest benefits and economies will be secured by standardizing the tools used to produce them, together with the reduction of variety as far as possible. To use a single cutter for all worms of a given pitch evidently would be the most economical procedure. In such a case, let p = axial pitch of worm, inches; α = half included angle of cutter; β = lead angle of worm; L = lead of worm, inches; f = width of flat at tip of cutter, inches; c = clearance, inches; D = nominal pitch diameter of worm, inches; a = nominal addendum, inches; W = working depth of thread, inches; H = whole depth of thread, inches; d = outside diameter of worm, inches; and r = root diameter of worm, inches. Then, when $c = a/6$,

$$W = \left(\frac{3}{7 \tan \alpha}\right)(p \cos \beta - 2f)$$

$$a = \frac{W}{2} = \left(\frac{3}{14 \tan \alpha}\right)(p \cos \beta - 2f)$$

$$H = W + c = \frac{13W}{12}$$

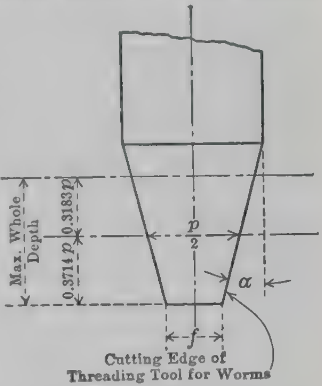

FIG. 62. Forms of threading cutters.

Figure 62 and Table 25 show satisfactory forms for threading cutters of the several thread angles.

Table 25. Dimensions of Threading Cutters (See Fig. 62)

Thread Angle, α	14 1/2°	20°	25°	30°
Tan α	.25862	.36397	.46631	.57735
Maximum whole depth	.6897p	.6897p	.6897p	.6897p
Maximum lead angle, β	15°	25°	35°	45°
Width of flat, f	.3079p	.2297p	.1537p	.0712p
$2f$	.6158p	.4594p	.3074p	.1424p
3/(14 tan α)	.82857	.58875	.45953	.37115

For worms which are to be made integral with the shaft, for lead angles less than 45 degrees, and where a shank hob is used to generate the gear, the formula $D = 2p + 0.5$ may be used. The AGMA recommends for worms to be mounted on the shaft, $D = 2.4p + 1.1$. In both cases, $d = D + W$; $\tan \beta = L/3.1416D$; $r = d - 2H$.

HOBBED WORMS. With the increasing use of multiple-threaded worms, where the number of threads on the worm may be 24 or more, the hobbing of worms is growing in favor. In this case, there is no reason why the standard spur and helical gear hobs should not be used to produce such worms, where lead angles are low. For higher lead angles, involute gear hobs with a pressure angle of 30 degrees would prove effective. The form of the basic rack could be the same as shown for the form of the 30-degree threading tool in Fig. 62. The sizes of such worms would be computed exactly the same as for helical gears, and the generating tool for the worm gear should be made to suit the worm thread form.

DESIGN OF WORM GEARS. The pitch diameter of the worm gear depends on the number of teeth in the gear and the axial pitch of the worm. Let D_g = pitch diameter of worm gear, inches; N = number of teeth in gear; and p = circular pitch (axial pitch of worm), inches. Then $D_g = pN/3.1416$. All other dimensions of the worm gear depend primarily upon the size of the worm and the center distance. When D = nominal pitch diameter of worm, inches; r = root diameter of worm, inches; c = clearance, inches; W = working depth of worm thread, inches; and C = center distance, inches, the dimensions shown in Fig. 63 become

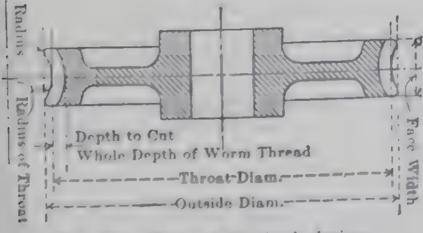

FIG. 63. Worm gear blank design.

$$\text{Throat diameter} = 2C - (r + 2c)$$

$$\text{Throat radius} = \frac{r}{2} + c$$

$$\text{Outside diameter} = \text{throat diameter} + \frac{W}{2}$$

Face width varies from 0.70D to 0.50D, depending on the rubbing speed of the worm. With increasing rubbing speeds, the face diameter should be reduced. The pitch diameter of the worm gear should lie between the diameter equal to $2C - D$ and the outside diameter of the worm gear. As noted before, the lower the pitch plane is placed on the worm thread, the greater is the load-carrying capacity and the smoothness of the action.

In general, the pitches commonly used on worm drives are much coarser than are required. The multiple-threaded and finer pitch worms are more efficient and run more smoothly than coarser pitch worms. To obtain the most effective worm drive, the pitch should be as fine as the strength of the gear teeth permits. For effective tooth action and full contact across the face of the worm gear, the sum of the number of teeth in the worm and worm gear should be not less than forty, approximately.

HOBS FOR WORM GEARS. The hob for a worm gear should be substantially a duplicate of the mating worm, but two precautions must be observed.

Nominal pitch diameter of the hob must never be less than that of the mating worm. If the hob is smaller, contact will be concentrated on the edges of the face of the worm, with attendant cutting or scoring and rapid wear. The amount which the hob can be made oversize depends largely on the lead angle of the worm. With low lead angles, it can be made appreciably larger, but with the high lead angles, it can be made only a very small amount oversize, unless the axis of the hob is to be twisted slightly in relation to the normal position of the axis of the worm. Such twisting will throw the initial contact toward the center of the worm face.

Length of the hob never should be less than the length of the mating worm in order to generate fully the contacting surfaces. This applies particularly when the worms are relatively short. In general, a hob whose length is six or seven times the axial pitch of the worm will be sufficiently long for all purposes. If the hobs are shorter, the worm should be made somewhat shorter than the hob. If a differential feed of the hob across the periphery of the worm gear is used, shorter hobs are satisfactory. Such hobs often are made as tapered hobs, thus combining the roughing and finishing operation. In such cases, the length of the full diameter of the hob plus the distance of differential feed should be slightly greater than the length of the mating worm.

LOAD-CARRYING CAPACITY OF WORM DRIVES. As with all other types of gearing, there are three limiting factors, any one or more of which may limit the capacity of the drive. These factors are heat of operation, beam strength of teeth, and surface endurance limits of materials. With worm drives, heat of operation and the surface endurance limits of the materials are the principal limiting factors.

On worm drives, rubbing velocity and pitch-line velocity must be considered. For simplicity, consider rubbing velocity to be equal to peripheral velocity at the nominal pitch diameter of the worm, although it varies at different points and may be greater or less than that used, depending upon the nature of the contact. Whence,

$$\text{Rubbing velocity in feet per minute} = 0.2618D \times \text{rpm}$$

where D = nominal pitch diameter of worm, inches, and rpm = revolutions per minute of worm.

$$V = \frac{L \times \text{rpm}}{12}$$

where V = pitch line velocity of worm gear, feet per minute, and L = lead of worm, inches.

The actual intensity of the dynamic load on worm-gear teeth is an open question. In the absence of more definite information, the following relation may be used: W = transmitted tooth load, pounds, and W_d = dynamic tooth load, pounds. Then

$$W_d = W\frac{1200 + V}{1200} \quad \text{for metal gears}$$

$$= W\frac{200 + V}{200 + 0.25V} \quad \text{for phenolic laminated material}$$

BEAM STRENGTH OF WORM-GEAR TEETH. The beam strength of worm-gear teeth may be determined by the Lewis equation. The safe static strength should be not less than the dynamic load. Let W_s = safe static tooth load, pounds; p = axial pitch of worm, inches; F = face width of worm gear, inches; S = flexural endurance limit of material, pounds per square inch; and y = tooth-form factor. Then

$$W_s = SpFy$$

For steady loads W_s should be about $1.25W_d$; for shock loads, W_s should be about $1.50W_d$.

With the changing forms and heights of the worm-gear teeth across the face, an exact tooth-form factor is a difficult value to obtain. For all practical purposes, where the sum of the number of teeth in the worm and worm gear is not less than 40, a constant value of y for each thread angle can be used:

Thread angle =	$14\frac{1}{2}$ degrees	20 degrees	25 degrees	30 degrees
y =	0.100	0.125	0.150	0.175

A hobbed worm gear never is generated completely. Its final finishing is obtained by its actual operation in position with its mating worm. For this reason, the materials used for worm gears should be such that they will conform to the worm without galling or excessive abrasion. Furthermore, the material of the worm should be smooth and hard enough to retain its form through such running-in or burnishing. A steel worm, therefore, to transmit power should have a Brinell hardness of not less than 250, and it should be as much harder as practicable.

Cast iron, manganese bronze, phosphor bronze, and some nickel bronzes, and several of the aluminum alloys have proved to be satisfactory materials for worm gears; the phenolic laminated materials prove very effective for the smaller gears and high-speed applications. Cast iron should not be used for rubbing velocities greater than about 1000 ft per min because of the danger of sparking. High-grade bronzes and aluminum alloys are essential for satisfactory results. A poorly alloyed material is practically worthless for a worm-gear material. Values for S are given in Table 26.

Table 26. Values of S for Worm Gears

Materials	S	Materials	S
Gray iron	12,000	Manganese bronze	17,000
Phenolic laminated material	6,000	Phosphor bronze	24,000

Values for nickel bronze and for the various alloys of aluminum suitable for worm-gear materials should be obtained from the manufacturers of the materials. It should be appreciated that increased physical strength obtained at the expense of lesser ductility of the material is of questionable advantage in materials to be used for worm gears. Also, the physical properties and structure of these materials depend more on the care and skill with which they have been alloyed, poured, and heat treated than upon the chemical analysis alone. Alloys of the same chemical analysis may have strength and wear values varying as much as two to one because of the difference in making and the difference in the resulting structure.

LIMIT LOADS FOR WEAR. Let W_w = limiting load for wear, pounds; D_g = pitch diameter of worm gear, inches; F = face width of worm gear, inches; K = load-stress value (Table 27). Then

$$W_w = D_g F K$$

The values of W_w should not be less than the dynamic load.

Table 27. Values of K for Worm Gears

Running with steel worms of 250 Brinell or higher

Material in Worm Gear	K	Material in Worm Gear	K
Cast iron	50	Phosphor bronze	100
Manganese bronze	80	Phenolic laminated material	125

EFFICIENCY OF WORM-GEAR DRIVES depends on several factors, such as the lead angle of the worm, the nature of the contact, intensity of the load, and speed of rubbing. When E = efficiency, β = lead angle of worm, f = coefficient of friction,

$$E = \frac{\tan\beta(1 - f\tan\beta)}{\tan\beta + f}$$

This applies to the efficiency at the tooth mesh only. The overall efficiency of a complete drive also must include the power losses of the thrust and radial bearings of both members of the drive.

The coefficient of friction will vary with the rubbing speed and with the load, and it follows closely the conditions existing on plain cylindrical bearings, except that the unit loads on worm-gear drives are much greater than those on plain bearings. The values in Table 28 represent average conditions. Table 29 shows the pronounced influence of the lead angle of the worm on the efficiency of the drive. These values are calculated from the foregoing equation, using the values of f given in Table 28.

Table 28. Values of the Coefficient of Friction f in Worm Drives

Rubbing Speed, ft/min	f	Rubbing Speed, ft/min	f	Rubbing Speed ft/min	f
5	.146	150	.045	1000	.041
10	.116	200	.042	1250	.046
20	.090	300	.040	1500	.050
40	.070	400	.036	1750	.054
80	.054	500	.033	2000	.058
100	.050	750	.036	2500	.065

A worm with a lead angle of 30 degrees is practically as efficient as one with 45 degrees. Lead angles less than 10 degrees are very inefficient.

The heat of operation of worm-gear drives would be estimated in the same manner as shown for spur gears, by determining values for the power loss in foot-pounds per minute and the exposed area of the case in square feet.

Table 29. Relation of Lead Angle, Speed, and Efficiency of Worm-gear Drives

BRITISH STANDARD. In worm gearing, the mating parts are so closely related that it is practically impossible to specify the tooth form of the gear without referring to the mating worm. The generating tool for the worm gear must be in all respects a counterpart of the worm. This problem has led to many controversies about the possibility or desirability of establishing design standards. The British Standards Institution established in 1937 a standard specification (B.S. 721-1937) for worm gearing based on a normal pressure angle of 20 degrees of the worm-thread form. Considerable leeway is given the designer in selection of proportions, such as number of teeth, number of threads, and the ratio of worm diameter to pitch selected, but formulas are given for strength and wear for each member.

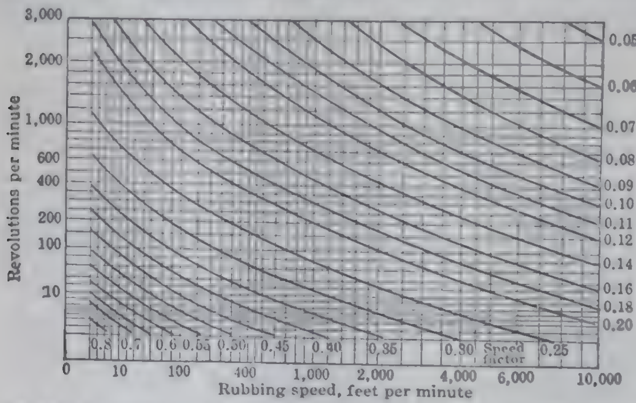

FIG. 64. Speed factors X_{cp} and X_{cw} for worm gearing. (From British Standards Institution Specification B.S. 721-1937, by permission)

The following formulas are taken by permission from the July 1941 revision of British Standard 721-1937, p. 22, and are applicable to 20-degree pressure angle worm gearing for a period of 12 hours a day under uniform load conditions:

Permissible Load for Wear

$$\text{For worm} = 0.18 S_{cp} X_{cp} f_{ew} D^{1.8} \text{ lb-in.}$$

$$\text{gear} = 0.18 S_{cw} X_{cw} f_{ew} D^{1.8} \text{ lb-in.}$$

where S_{cp} and S_{cw} are surface stress factors from Table 30.

X_{cp} and X_{cw} are speed factors reflecting revolutions per minute and rubbing speed. See Fig. 64.

$$f_{ew} = \text{maximum effective face width (see Fig. 65)}$$
$$= 2m\sqrt{q} + 1$$

where m = module = 0.3183 × axial pitch; q = worm pitch diameter per module.

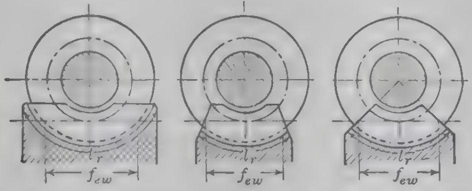

FIG. 65. Face factor, f_{ew}, for worm gearing. (From British Standards Institution Specification B.S. 721–1937, by permission)

Permissible Load for Strength

$$\text{For worm} = 0.625 S_{bp} X_{bp} l_r m D \cos \lambda \text{ lb-in.}$$
$$\text{gear} = 0.625 S_{bw} X_{bw} l_r m D \cos \lambda \text{ lb-in.}$$

where S_{bp} and S_{bw} are bending stress factors for the material as listed in Table 30.

Table 30. Stress Factors for Worm Gears

	Material	Bending Stress Factor per sq in. S_b lb	Surface Stress Factor (S_c) When Running with				
			A	*B*	*C*	*D*	*E*
A	Phosphor bronze, sand cast	7,000	.....	600 *	600	700	1,400
	Phosphor bronze, chill cast	8,500	.....	800 *	800	900	1,600
	Phosphor bronze, centrifugally cast	10,000	.....	1,000 *	1,000	1,100	2,000
B	Cast iron (gray)	6,000	900 *	600 *	600 †	600 †	750 †
C	0.4% Carbon steel normalized	20,000	1,400	900 †	.....	.....	.....
D	0.55% Carbon steel normalized	22,000	2,000	1,100 †	.....	.....	.....

	3 1/2% Nickel case-hardening steel	40,000	6,500	4,000 †	.....	.....	2,000 †
	5% Nickel case-hardening steel	47,000	7,000	4,000 †	.....	.....	2,000 †
	3 1/2% Nickel chromium case-hardening steel	47,000	7,000	4,000 †	.....	.....	2,000 †
	High nickel chromium case-hardening steel	47,000	8,000	4,000 †	.....	.....	2,000 †

* Maximum permissible rubbing speed = 500 ft per min.
† Should not be used except for hand motions.

X_{bp} and X_{bw} are speed factors for the worm and wheel to be selected from the charted data shown as Fig. 66.

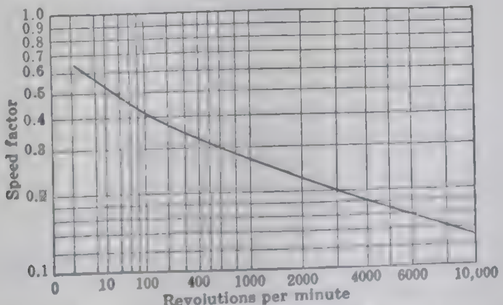

FIG. 66. Speed factors X_{bp} and X_{bw} for worm gearing. (From British Standards Institution Specification B.S. 721–1937, by permission)

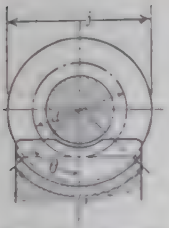

FIG. 67. Length of root of worm-wheel teeth, l_r. (From British Standards Institution Specification B.S. 721-1937, by permission)

l_r is the length of the root of worm-wheel teeth on cross section of rim (see Fig. 67) and may be calculated from this formula:

$$l_r = (j + 2c)\sin^{-1}[f_w/(j + 2c)]$$

where j = outside diameter of worm; $c = 0.2m \cos\lambda$; f_w = face width of wheel; and λ = lead angle of worm threads.

Horsepower rating for the gear set is then established by using the smallest of the permissible torque ratings designated as M_w in the formula

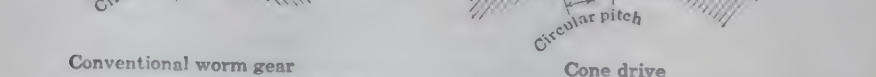
$$\text{Horsepower} = \frac{M_w N}{63{,}000}$$

HOURGLASS OR GLOBOID WORM DRIVES. In an hourglass or globoid worm drive, neither member of the pair has a uniform helical lead of tooth along its axis. One or both members may be made to envelop the other. The contact is line contact, and the pitch surfaces are indeterminate. No fixed pitch point exists. Each different design must be analyzed individually to establish the nature of the action and position of the contact. The motion is primarily that of a barrel cam operating against a series of cam followers free to rotate about an axis.

The earliest type of such a drive is the Hindley worm. Many other later drives of this type have been designed. Each different drive of this type has so many individual features that they require individual analyses to determine the exact nature of the contact, etc. Also their production requires special manufacturing facilities. In all such drives, however, the maximum theoretical contact that can be obtained is line contact.

Double-enveloping Gearing

CONE-DRIVE GEARS. Cone-Drive (Ref. 31) is the trade name for a right-angle drive double-enveloping gearing. The basic principle of the Cone-Drive embodies a rational method of producing a double-enveloping gear drive having full mating capacity without modifications or limitations (Fig. 68).



Conventional worm gear

Cone drive

FIG. 68. Cone-Drive gearing compared with conventional worm gear. (Courtesy of Michigan Tool Co.)

The manufacturing process is such that the hob or cutter is in the same relative position to the part being generated as the mating part will occupy when the set is mounted in operating position. Thus pinion and gear teeth are generated on operating centers in geared time relation. The hob and cutter have thinner teeth than the space to be generated, and use side feeding to develop proper tooth thickness.

The general design characteristics of Cone-Drive gearing (Fig. 69) may be summarized as follows.

Pressure angle is always 20 degrees in the normal section. This has been established after consideration of the effect of pressure angle on load distribution in the pinion root, gear teeth, and bearings. Thus no consideration need be given to changes in pressure angle when working on manufacturing processes or tools.

Number of teeth selected for the gear for a given ratio and center distance has no effect except on economy of manufacture. The load-carrying capacity, mechanical strength, and total area of contact of a Cone-Drive remain unchanged, regardless of the number of teeth in the gear and threads in the pinion. Thus the number of teeth can be selected on the most economical basis.

Circular pitch is not considered in designing a Cone-Drive gear set. The "correct" pitch is automatically obtained by designing the gearing from the standpoint of correct proportioning, ratio, stresses, and number of teeth desired. It is a result, not a specification.

Tooth thickness in both the gear and the pinion is controlled by the manufacturing operation and is independent of hob or cutter design. It can be varied at will. Tooth thickness, therefore, can be and is varied to balance stresses resulting from the use of different materials in the gear or pinion.

A so-called soft pinion is used in Cone-Drives. This pinion, which is the result of exhaustive tests and experiments, is in line with the principle that when wear occurs in this drive, each member tends to regenerate the correct form in the other. The pinion is made of deep-hardening alloy steel which is heat treated to 35-38 Rockwell C scale before the threads are generated. This eliminates heat-treating errors and gives a satisfactory coefficient of friction.

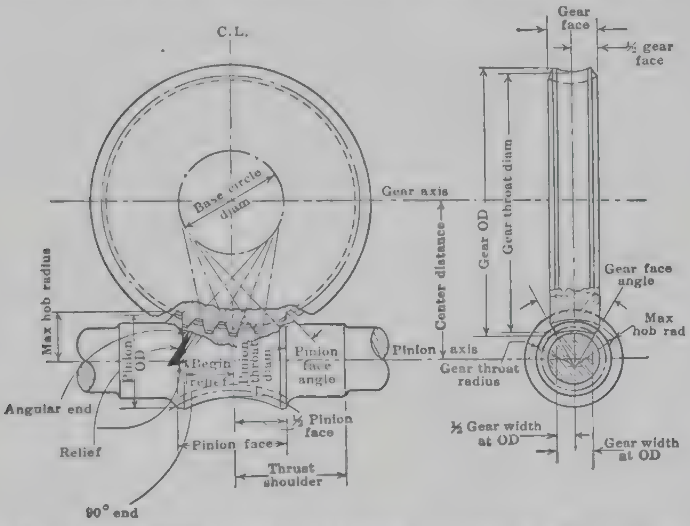


FIG. 69. Nomenclature of Cone-Drive gearing. (Courtesy of Michigan Tool Co.)

Load-carrying ability of Cone-Drive gearing is based on a combination of factors including pinion revolutions per minute, gear ratio, velocity factor, and pressure constants. Stress analysis of gears at rated load shows a fiber stress in the gear teeth of approximately 8000 psi at zero rpm, and a corresponding stress in the pinion root under 30,000 psi. When designing for static load conditions or extremely low speeds, the capacity may, therefore, be materially increased to the point where the fiber stresses in the gear teeth approach 75% of the yield point of the material.

Horsepower is calculated from the formula

$$\text{Horsepower} = \frac{\text{Speed}}{\text{Gear ratio}} \times KNf$$

where K is a pressure constant ranging from 0.12 for a 3-in. center distance to 500 for a 40-in. center distance gear set; N is a ratio correction factor which ranges from 0.70 to 0.76 for ratios of 10 : 1 to 100 : 1; and f is a velocity correction factor which varies with center distance and speed.

Efficiency of Cone-Drive gearing is dependent primarily on the helix angle of the pinion. Between 10 and 55 degrees helix angle, efficiency ranges from 91 to 97.5%. From 5 to 10 degrees helix angle, the efficiency ranges from 83 to 91%. These figures are for pinion speeds up to 2400 rpm. Below 1500 rpm the efficiency drops approximately 1% for each 200 rpm, and below 1000 rpm the efficiency drops about 1% for each 100 rpm.

The double-enveloping characteristic of Cone-Drive gearing usually results in a resemblance to hour-glass worm gearing. In some cases of extreme ratios the drive may resemble right-angle helical gearing, although even in these constructions the double-enveloping characteristics are retained.

Analysis of contact lines shows that every point on the pinion (within the unrelieved load-carrying section) contacts some portion of the gear tooth in addition to the midplane through which all points on the pinion pass. In its passage across the gear tooth some point of this section of the pinion also touches every point on the gear-tooth face.

The materials ordinarily used for Cone-Drive gearing up to pinion speeds of approximately 2000 fpm consist of a high-quality gear bronze which develops minimum physica properties on the order of 50,000 psi tensile strength. The pinion is usually made from a chrome-nickel-molybdenum steel, heat treated to a minimum hardness of 32 Rockwell C and 140,000 psi tensile strength.

At slow speeds (under 250 ft per min rubbing velocity), the material combinations may use a pinion of aluminum bronze, running with a 0.40 to 0.50% carbon steel gear, or an electric furnace iron casting.

Where pinion speeds in excess of 2000 fpm are encountered, a special gear bronze, containing 10% lead, is recommended.

For general service conditions up to 2000 ft per min rubbing speed of the pinion a pure Pennsylvania oil having a viscosity of 150 SSV at 210 F is recommended. The addition of 5 to 7% acidless animal fat is said to improve the operating characteristics of this lubricant. The design of Cone-Drive gearing is such that the entering thread provides a tapering oil film wedge ahead of the load-carrying contact area, thus providing improved lubrication.

9. GEAR TRAINS AND APPLICATION DATA

SIMPLE GEAR TRAINS are usually referred to as being one pair of mating gears having essentially one-tooth mesh area. In parallel externally toothed gearing (Fig. 14) the direction of rotation of the mating elements is opposite and the speed ratio is in inverse proportion to the numbers of teeth in each member. Where an internal gear (Fig. 24) is used, the direction of rotation is the same for each member, and the speed ratio is again in inverse proportion to the numbers of teeth in the mating gears.

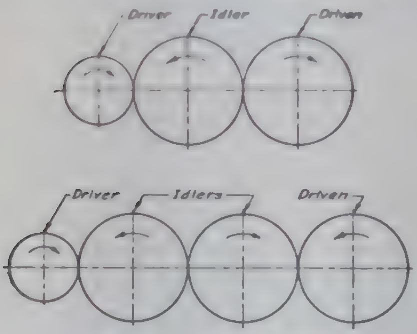

Fig. 70. Idler gear trains.

IDLER GEAR TRAINS (Fig. 70) are often used where it is necessary to maintain direction of rotation between the driving and driven members or, in other cases, where the center distances between the shafts suggest the introduction of an idler to maintain size and velocity of the gear members within reasonable limits.

The speed ratio of gear trains using idlers is in proportion to the driving and driven members only. Where multiple idlers are used in even numbers, the direction of rotation of the driven gear is opposite the driver; and when the number of idlers is odd, the direction of rotations is the same.

RIGHT-ANGLE DRIVES employing bevel gearing follow the same pattern as simple gear trains, as described above, but, in addition (Figs. 32, 33, 34), each mesh point changes the angle between the supporting shafts.

MULTIPLE REDUCTIONS are obtained by compounding series of simple trains as shown in Fig. 71. To obtain overall speed ratios and directions of rotation, it is necessary only to consider each set as a simple train and to follow the motion from driving member through to the driven member.

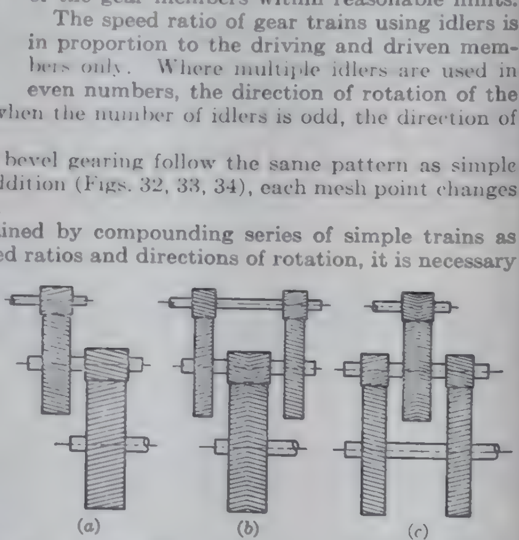

Fig. 71. Multiple-reduction gear trains: (a) single helical gears; (b) herringbone with divided high-speed gear set; (c) herringbone with divided low-speed gear set.

HELICAL OR BEVEL GEAR types require consideration of the amount and direction of the end thrust. Where double-reduction gear sets of the single-helical type are involved (see Fig. 21), the hand of the helix of the driven member of the high-speed train and the driving member of the low-speed set should be the same so as to offset the thrust developed in each.

HERRINGBONE gear trains should be arranged so that the apex of the Vee formed by the two helices is in the direction of rotation (see Fig. 23), thus avoiding excessive corner contact loading that might be caused by deflections.

MULTIPLE-TOOTH CONTACT gear trains are finding many practical uses, particularly where space and weight requirements justify the added cost related to precision work. Where multiple-contact systems are used without an internal gear (Fig. 72), they are often called multiple jack-shaft gear trains. They should be analyzed, using the formulas applying to simple trains, except in load-carrying ability where the division of the load between the various contacts must be studied in arriving at tooth contact stresses. It is generally thought practical to apply a factor of 0.90 to 0.95 (depending on accuracy) to the loading factor, based on uniform load distribution.

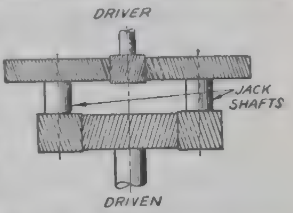

FIG. 72. Multiple-contact gear trains.

PLANETARY OR EPICYCLIC GEAR TRAINS may be defined as trains of wheels in which some or all of the wheels have a motion compounded of a rotation about an axis and a revolution of that axis. They are employed to produce large speed ratios with few parts. The link, or planet carrier arm, usually rotates about the axis of one of the gears, which may be fixed. The output gear may or may not be placed on this axis, depending upon whether pure rotation or a cycloidal output motion is desired. The name epicyclic used in connection with planetary gear trains has no connection with the form of the gear teeth, which may be cycloidal, involute, or any other system.

Speed calculations for planetary trains are complicated by the fact that the line of centers of the gears usually rotates. A variety of methods has been developed, of which the principal ones are outlined in the following pages.

Relative Angular Velocity Method. Either a tabular or a formula method may be used to solve directly for angular velocity ratios.

In the tabular method the planetary train is subjected to two imaginary operations: (1) the entire unit, with the gears locked against relative rotation, is turned through one complete revolution; and (2) with the carrier arm held stationary and the gears unlocked, the gear which is intended to be fixed in actual operation is turned back one revolution, thus restoring it to its original position. At the same time the corresponding rotations of the other gears in the train are calculated from their arrangements and number of teeth (see p. 14-48). Both steps are recorded in tabular form and the net effect determined by algebraic summation.

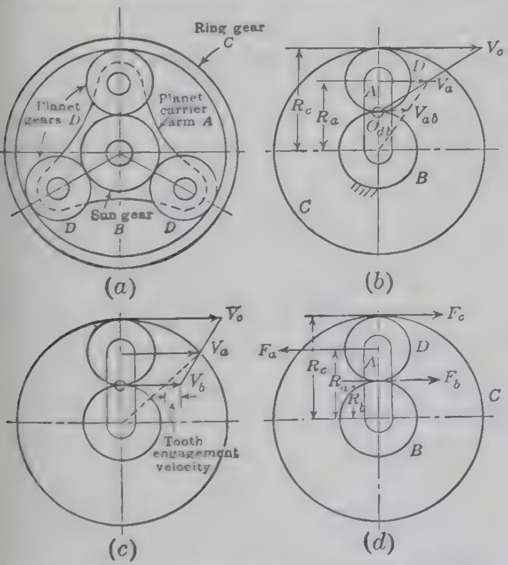

FIG. 73. Simple internal-external planetary system.

EXAMPLE 1. In a simple planetary train (Fig. 73*a*) it is assumed that sun gear B is fixed to the frame of the machine, ring gear C is the input, and planet carrier arm A is the output. It is required to find the speed ratio of input to output. The results of the two-step procedure just described are shown in the accompanying table, in which the number of teeth in each gear or pinion is denoted by the identifying letter on the figure; thus, B denotes the number of teeth in gear B. In completing the second line it is important to place the proper sign in front of each term. This is found by inspection of the figure and observation of the relative direction of rotation of each gear. Thus both ring gear C and planet pinion D rotate opposite to sun gear B (with respect to the arm A) and carry a plus sign since the rotation of B carries a minus sign. From the last line of the table, while arm A rotates +1 revolution the ring gear C rotates $1 + (B/C)$ revolution, which is the required ratio.

	A	B	C	D
Step 1. Train locked	$+1$	$+1$	$+1$	$+1$
Step 2. Train unlocked, carrier arm fixed	0	-1	$+\frac{B}{C}$	$+\frac{B}{D}$
Resultant	$+1$	0	$1+\frac{B}{C}$	$1+\frac{B}{D}$

EXAMPLE 2. In the compound planetary train shown in Fig. 74*a* the sun gear *B* is the input, the outer ring gear *C* is fixed, and the inner ring gear *G* is the output. The carrier arm *A* rotates freely. It is desired to calculate the ratio of input speed (of *B*) to output speed (of *G*). In the accompanying

	A	*B*	*C*	*G*
Step 1. Train locked	+1	+1	+1	+1
Step 2. Train unlocked, arm fixed	0	$+\frac{C}{B}$	−1	$-\frac{CE}{DG}$
Resultant	+1	$1+\frac{C}{B}$	0	$1-\frac{CE}{DG}$

table only the gears which are involved in the problem are listed. Gear *C* being fixed is given one minus turn in the second line while the arm *A* is held stationary. From the last line of the table the required speed ratio is

$$\frac{1+\frac{C}{B}}{1-\frac{CE}{DG}} = \frac{1+\frac{120}{12}}{1-\frac{120 \times 43}{54 \times 109}} = 89.2$$

A general formula may be written relating the speed or angular velocity of the planet carrier arm *A* to any two of the gears on the same axis. With the two gears denoted by *B* and *C*, the formula is

$$\omega_{af} = \frac{\omega_{bf} - \left(\frac{\omega_{ba}}{\omega_{ca}}\right)\omega_{cf}}{1 - \left(\frac{\omega_{ba}}{\omega_{ca}}\right)} = \frac{\omega_{bf} - k\omega_{cf}}{1-k} \qquad (1)$$

where ω_{af} = speed of carrier arm *A* relative to frame of the machine, *F*; ω_{bf} = speed of gear *B* relative to frame; ω_{cf} = speed of gear *C* relative to frame; ω_{ba} = speed of gear *B* relative to arm *A*; ω_{ca} = speed of gear *C* relative to arm *A*; $k = \omega_{ba}/\omega_{ca}$ = speed ratio of the two gears calculated with the carrier arm stationary. In applying the formula it is not necessary to calculate ω_{ba} and ω_{ca} individually; only their ratio *k* is needed. It will be observed that the calculation of *k* corresponds to Step 2 in the tabular solution already described. If there are only two gears of the sun or ring type it is convenient to designate them *B* and *C* so that the formula can be applied direct. If there are more than two such gears so that another letter is needed it is necessary only to substitute the new letter for either *b* or *c* in each of the subscripts. In such event, of course, *k* has a different value and should be denoted by *k′* or *k″*. The formula takes care of only two gears at a time, hence must be rewritten for each additional gear. This is illustrated in Example 4, p. 14-51.

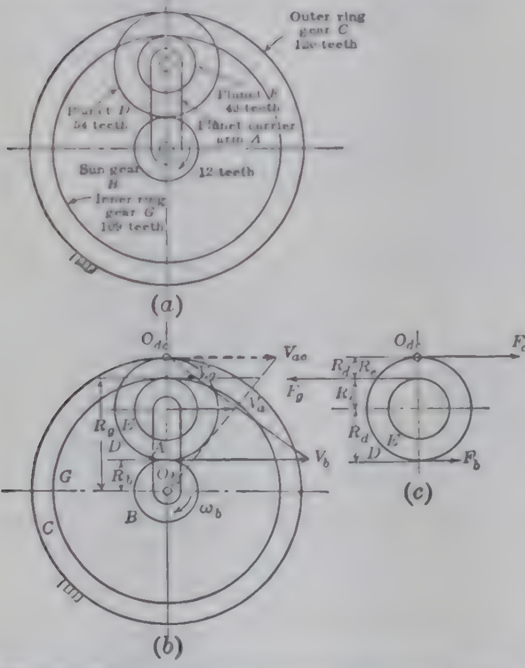

FIG. 74. Compound internal-external planetary system.

EXAMPLE 3. If the formula is applied to the problem stated in Example 1, it is noted that $\omega_{bf} = 0$, ω_{cf} is unknown input, $\omega_{af} = 1$, and $k = -C/B$. Substituting,

$$1 = \frac{0-(-C/B)\omega_{cf}}{1-(-C/B)} \quad \text{from which } \omega_{cf} = 1 + \frac{B}{C} \text{ as before}$$

The formula method is particularly convenient if both gears are driving, as in differential drives. Thus, if in this example gear *B* turns at 1000 rpm and gear *C* at 600 rpm, the resultant speed of arm *A* can be determined by direct substitution in the formula, letting $\omega_{bf} = 1000$ and $\omega_{cf} = 600$, *k* being already known.

Example 4. If eq. 1 is applied to the problem stated in Example 2, it is noted that $\omega_{cf} = 0$, hence

$$\omega_{af} = \frac{\omega_{bf}}{1 - \dfrac{\omega_{ba}}{\omega_{ca}}}$$

This gives the speed of the arm but not that of the ring gear G, which is the output. It is therefore necessary to rewrite the equation to bring in the gear G. This can be done by simply substituting g for b in the subscripts of the equation, giving

$$\omega_{af} = \frac{\omega_{gf}}{1 - \dfrac{\omega_{ga}}{\omega_{ca}}}$$

Since the arm A rotates freely it is not necessary to know ω_{af} for present purposes; hence it may be eliminated by equating the two foregoing expressions, as shown below. By inspection of Fig. 74a it is evident that $\omega_{ba}/\omega_{ca} = -C/B$, and $\omega_{ga}/\omega_{ca} = +CE/DG$. Substitution in the two preceding formulas gives the result

$$\frac{\omega_{bf}}{\omega_{gf}} = \frac{1 - \dfrac{\omega_{ba}}{\omega_{ca}}}{1 - \dfrac{\omega_{ga}}{\omega_{ca}}} = \frac{1 + \dfrac{C}{B}}{1 - \dfrac{CE}{DG}} = \frac{1 + \dfrac{120}{12}}{1 - \dfrac{120 \times 43}{54 \times 109}} = 89.2$$

Instant Center and Linear Velocity Method. This method (Ref. 32) permits either a graphical or an analytical solution and in addition readily furnishes information on pitch line velocities of tooth engagement. It has the further advantage of affording a visual check of the directions of motion of each element.

Figure 73b, which represents the mechanism of Fig. 73a in skeleton form, shows that the pitch point O_{db} of the planet pinion D and the fixed sun gear B is the instant center of rotation of the planet pinion. Therefore the linear velocity of each point on the planet pinion is proportional to its distance from O_{db}. If the pitch line velocity of the ring gear C ($V_c = \omega_c R_c$) is known, the simple graphical construction shown gives, by similar triangles, the velocity of any other point, such as the center of the planet pinion on the carrier arm, V_a. Angular velocity of the planet carrier arm is V_a/R_a, and the speed ratio of ring gear to carrier arm therefore is $(V_c/R_c) \div (V_a/R_a) = (V_c/V_a)(R_a/R_c)$. The ratios of velocity and radii can be readily determined from the geometry of the figure if an analytical solution is desired.

Pitch line velocity of engagement of the teeth is found by constructing a radial line (shown dotted in Fig. 73b) from the center of rotation of the carrier arm through the tip of the V_a vector. A vector V_{ab} drawn from the pitch point O_{db} represents the velocity of the carrier arm at the pitch radius of the fixed sun gear B and therefore represents the pitch line velocity of engagement.

When both sun and ring gears are driving, as in a differential drive, it is necessary only to calculate the linear velocities of each, plot the vectors V_b and V_c at the two pitch points, and determine the velocity of the planet pinion center, V_a, as shown in Fig. 73c. The pitch line velocity of tooth engagement is found as before by drawing a radial line from the center of rotation of the carrier arm (shown dotted). A vector from the pitch point to this dotted line represents the velocity of the carrier arm at this radius; therefore the pitch line velocity of tooth engagement is the vector difference between this velocity and V_b.

Example 5. Solution of the problem stated in Example 2, by the method of instant centers and linear velocities, is indicated in Fig. 74b. Vector $V_b = \omega_b R_b$ is drawn to represent the pitch line velocity of the sun gear B. The instant center of the planet cluster being at O_{dc}, the velocity at any point on the cluster is found by drawing a straight line from O_{dc} to the tip of the V_b vector and constructing a vector line parallel to V_b. The angular velocity of the output gear G is found from the figure, $\omega_g = V_g/R_g$, and the required angular velocity ratio is $\omega_b/\omega_g = (V_b/V_g)(R_g/R_b)$. Ratios of velocities and radii are readily determined from the geometry of the figure.

To find pitch line velocities of engagement a radial line (shown dotted) is drawn through the tip of the V_a vector from the center of rotation of the carrier arm. Since ring gear C is fixed, the velocity of the carrier arm at this radius, V_{ac}, represents the engagement velocity of gear C. The engagement velocity of gear B is the vector difference between V_b and the arm velocity at the radius of gear B. Inspection of the figure will show that this is the same as the engagement velocity for C, which is as it should be since both B and C engage the same planet pinion D. In like manner the engagement velocity of gear G is the vector difference between the velocity of the arm at radius R_g and the velocity V_g.

Forces and Moments. Static force and torque relationships furnish another viewpoint on planetary gearing, and can be employed to determine speed ratios. In the simple system of Fig. 73d it is evident that for the planet to be in equilibrium the forces at the two pitch points must be equal to each other and together equal and opposite to the force at the pinion center, that is, $F_b = F_c$ and $F_b + F_c = F_a$. Torque on each element is equal to the force times the radius to the center of rotation; hence the input torque is $T_c = F_cR_c$, the output torque is $T_a = -F_aR_a$, and the reaction torque on the fixed sun gear is $T_b = F_bR_b$. Torque ratio between output and input is $T_a/T_b = F_aR_a/F_bR_b$, which may be written $(F_a/F_b)(R_a/R_b)$. The force ratios are readily determined from the equilibrium of the planet, and the radius ratios from the geometry of the planetary set. Torque ratio of output to input is also equal to speed ratio of input to output, assuming no internal losses, hence the torque calculations offer a method of calculating speeds.

EXAMPLE 6. Solving by force and torque relationships the problem stated in Example 2, the free-body diagram for the pinion cluster is shown in Fig. 74c. Taking moments about pitch pint O_{dc}, $F_b \times 2R_d = F_g(R_d - R_e)$, from which $F_g = F_b \times 2R_d/(R_d - R_e)$. The output torque is F_gR_g and the ratio of output to input torques is $T_g/T_b = F_gR_g/F_bR_b = (F_g/F_b)(R_g/R_b)$. From the analysis of pinion equilibrium, $F_g/F_b = 2R_d/(R_d - R_e)$, hence $T_g/T_b = 2R_dR_g/R_b(R_d - R_e)$, which may be calculated from the geometry of the figure. Pitches being equal for all gears, the radii may be replaced by the numbers of teeth, or $T_g/T_b = 2 \times 54 \times 109/12(54 - 43) = 89.2$.

LIMITATIONS ON PLANETARY GEAR RATIOS.* In a simple system of planetary gears, such as is shown in Fig. 73a, three alternatives are possible. Sun gear B can be stationary with ring gear C driving the carrier arm A in the same direction; ring gear C can be stationary with sun gear B driving the carrier arm in the same direction; or carrier arm A can be stationary with ring gear C and sun gear B rotating in opposite directions. With the notation B = number of teeth in gear B, etc., the following formulas give the speed ratios for each alternative arrangement:

Ring gear stationary $$\frac{\omega_b}{\omega_a} = k_1 = 1 + \frac{C}{B}$$

Sun gear stationary $$\frac{\omega_c}{\omega_a} = k_2 = 1 + \frac{B}{C}$$

Arm stationary $$\frac{\omega_b}{\omega_c} = k_3 = -\frac{C}{B}$$

A reversing drive (arm stationary) always has a speed ratio numerically smaller by one than a unidirectional drive with gears of similar proportions, and ring gear stationary.

Maximum Number of Planet Pinions. To avoid interference between the teeth of adjacent planet pinions, the speed ratio with standard addendum teeth (addendum = one/diametral pitch) must be less than

$$k_{1\max} = \frac{2B - 4}{B\left[1 - \sin\left(\frac{180}{n}\right)\right]} \tag{2}$$

where n is the number of equally spaced planet pinions. Table 31 lists maximum ratios k_1 computed for two to six planet pinions and with 12, 15 or 20 teeth in the sun gear B.

Table 31. Maximum Ratio k_1 † for Simple Planetary

No. of Planet Gears	Ratio k_1		
	$B = 12$	$B = 15$	$B = 20$
2	∞	∞	∞
3	12.37	12.93	13.43
4	5.68	5.92	6.14
5	4.04	4.21	4.37
6	3.33	3.47	3.60

† k_1 is the ratio of sun gear speed to carrier arm speed when the ring gear is stationary.

Equal Spacing of Planet Pinions. For equal spacing the following relation between the numbers of teeth in the sun gear and the planet pinion must be observed:

$$\frac{2(B + D)}{n} = \text{an integer} \tag{3}$$

where n is the number of equally spaced planet pinions, B is the number of teeth in the sun gear, and D is the number of teeth in the planet pinion. Number of teeth, C, in the ring gear is given by the relation $C = 2D + B$.

---

* Contributed by George S. Hoell.

Table 32 gives the speed ratio k_1 for various combinations of sun and planet gears, together with the number of equally spaced planet pinions that can be used with each. The ratio k_1 is the speed of the sun gear if the carrier arm speed is unity and the ring gear is fixed. For values beyond the range of the table the equation $k_1 = 2[1 + (D/B)]$ may be used. If more than two planets must be used the limiting ratio due to possible interference should be checked by Eq. 2.

EXAMPLE 7. It is desired to obtain a speed reduction k_1 equal to approximately 4.2, using as many planet pinions as possible to carry the load. From Table 31 the sun gear must have at least 15 teeth if it is desired to use five equally spaced planet gears. If four planets are sufficient, the sun gear may have fewer teeth. Table 32 allows the use of four planets with 20 teeth in the sun gear and 22 in each of the planet pinions, at a ratio of 4.2. If the ratio requirement is not exact and five equally spaced planets are desired, Table 32 shows that 19 teeth in the sun gear and 21 in each of the planet gears give a ratio of 4.211 and permit use of five planets.

Table 32. Ratio k_1 and Allowable Number of Planets *

* The upper figure of each pair is the ratio k_1; the lower figures indicate the number of planets which may be used equally spaced.

WORM-GEAR TRAINS provide large reductions in a single gear set inasmuch as the speed ratio of this type of gearing is the ratio between the number of teeth in the wheel and the number of threads in the worm.

GEARED POWER TRANSMISSIONS have become very popular, and the AGMA has established recommended practices for the proportions, rating, and application of the more popular types, including helical and herringbone spur gear, planetary, combination helical and bevel, and worm gear constructions. The combination of a geared reduction unit and an electric motor, generally known as a gearmotor or a motorized speed reducer, has given industry a compact unit, representative of the application possibilities of geared mechanisms.

STANDARD SPEED-REDUCING mechanisms of many types are available, and it will be the purpose of the following brief outlines of typical constructions to familiarize the reader with some of the more popular design arrangements.

Single-reduction parallel shaft types are available with single helical or herringbone gear trains and with shafts in either the horizontal or vertical planes. Ratios generally are under 10 to 1, and standard sizes run upwards of 500 hp.

Double-reduction parallel shaft types (Fig. 71) employ various construction arrangements. Some designs use single helical gears in both sets, Fig. 71*a*. Others use herringbone gear sets in tandem. Generally speaking, the most popular type because of its balanced loading is that shown in Fig. 71*c*, wherein the low-speed double helical gear set (essentially herringbone in action) spans the high-speed herringbone train. Ratios for standard reducers of the double-reduction type are usually limited to a range between 10 to 1 minimum and 60 or 90 to 1 maximum. Horsepower capacities approach 500 for standard makes.

Triple-reduction designs follow the double-reduction gearing arrangements with the additional gear set often nested between the high-speed and intermediate shafts of the double trains, thus conserving space. Speed reduction ratios for these units run between 80 to 1 and 500 to 1, with horsepower capacities of over 100 being available in standard units.

Gearmotors or motorized speed reducers are available from many sources in horsepower ranges up to 75 and in output speeds down to 13.5 rpm. Generally speaking, the standard models consist of single-, double-, and triple-reduction constructions.

Other Types. It is obviously impossible to cover in a handbook all the constructions used in standard industry practice. We might call attention to the availability of vertical geared units, worm-gear units, combination helical and right-angle drives, and many other ingenious arrangements that have become widely used. The reader interested in data on these equipments is referred to the general catalogs of industry.

10. FINE-PITCH GEARING

Fine-pitch gears have been defined as gears of 20 diametral pitch and finer, by the AGMA. Although there is no mathematical difference between fine- and coarse-pitch gears of involute form, fine-pitch gears require special considerations for the following reasons.

A. Greater clearances are required than for coarse-pitch.

B. Consideration must be given to point widths of gear cutting tools and to top lands of gears, especially to top lands of enlarged heat-treated pinions.

C. Fine-pitch gears require different production and inspection techniques from coarse-pitch gears, except in the coarser range of fine-pitch gears. Their use is generally for the transmission of motion rather than power. Surface durability is of far greater importance than beam strength.

The AGMA has developed a number of standards to meet the requirements of fine-pitch gears. Standard 470.01 establishes clearances for all 20-degree pressure angle fine-pitch gears of 20 DP and finer, except bevel gears. Greater clearances than for coarse-pitch gears are required to allow for

A. Greater wear on point of generating tool.

B. Fillet radius produced by dull generating tool is greater than derived from formula 0.157/DP.

C. Accumulation of foreign matter at bottom of teeth.

AGMA Standard 207.01 establishes the tooth form for fine-pitch involute spur and helical gears of 20-degree normal pressure angle. Table 33 gives the standard tooth pro-

Table 33. Standard Tooth Proportions for Fine-pitch Gears

N = number of teeth in gear
P = diametral pitch
n = number of teeth in pinion
Dimensions are in inches.

Addendum	$\frac{1.000}{P}$	Whole depth	$\frac{2.200}{P} + 0.002$	Pitch diameter	$\frac{N}{P} : \frac{n}{P}$
Dedendum	$\frac{1.200}{P} + 0.002$	Clearance	$\frac{0.200}{P} + 0.002$	Outside diameter	$\frac{N+2}{P} : \frac{n+2}{P}$
Working depth	$\frac{2.000}{P}$	Tooth thickness on pitch diameter	$\frac{1.5708}{P}$	Center distance	$\frac{N+n}{2P}$

portions for this system. Pinions having seventeen or fewer teeth are enlarged in accordance with Table 34. Two options are given in this standard:

A. Standard center distance system (long and short addendum).
B. Enlarged center distance system.

Table 34. 20-Degree Pressure Angle Involute Fine-pitch System for Spur Gears

Dimensions Required When Using Enlarged Pinions

The outside diameters of small pinions are enlarged to avoid undercut. To maintain standard center distances when using enlarged pinions, the mating-gear diameters must be decreased by the amount of the pinion enlargement. If mating gears are made with standard tooth proportions, the center distances must be increased as shown below. Tabular values are in inches for 1 DP. For other pitches, divide tabular values by the diametral pitch.

Number of Teeth	Pinion Dimensions		Standard Center Distance System (Long and Short Addendum) Gear Dimensions				Enlarged Center Distance System Standard Mating Gear Diameter	
	Outside Diameter	Cir. Tooth Thickness at Standard Pitch Diameter	Decrease in Standard Outside Diameter	Cir. Tooth Thickness at Standard Pitch Diameter	Recommended Minimum No. of Teeth (N_g)	Contact Ratio N_p Mating with N_g	Increase Over Standard Center Distance	Contact Ratio N_p Mating Itself
10	12.8302	1.8730	.8302	1.2686	33	1.419	.4151	1.135
11	13.7132	1.8304	.7132	1.3112	30	1.450	.3566	1.186
12	14.5963	1.7878	.5963	1.3538	27	1.473	.2982	1.238
13	15.4793	1.7452	.4793	1.3964	25	1.493	.2397	1.290
14	16.3623	1.7027	.3623	1.4389	23	1.508	.1812	1.344
15	17.2453	1.6601	.2453	1.4815	21	1.516	.1227	1.398
16	18.1284	1.6175	.1284	1.5241	19	1.519	.0642	1.436
17	19.0114	1.5749	.0114	1.5667	18	1.522	.0057	1.511

Each system has some advantages and disadvantages over the other. The standard does not recommend the use of pinions having fewer than ten teeth. Almost all the advantages of the involute curve are lost when pinions having fewer than ten teeth are enlarged to avoid objectionable undercut.

ENLARGEMENT OF HELICAL PINIONS OF 20-DEGREE NORMAL PRESSURE ANGLE. The enlargement of helical pinions to avoid undercut cannot be tabulated as simply as for spur pinions because of the wide range of helix angles used. It is recommended that helical pinions be enlarged in accordance with Fig. 75.

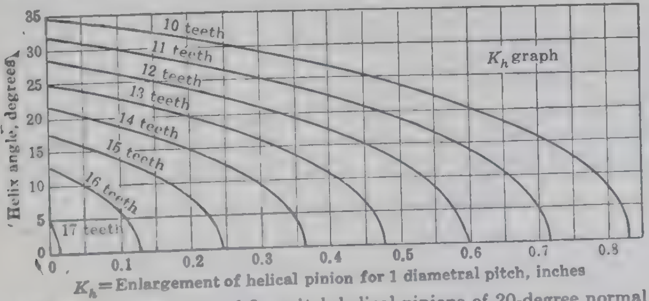

FIG. 75. Enlargement of fine-pitch helical pinions of 20-degree normal pressure angle. (AGMA Standard 207.01)

Notation

n = number of teeth
P_n = normal diametral pitch
P_t = transverse diametral pitch
ψ = helix angle
d = pitch diameter
d_o = outside diameter
K_h = enlargement of helical pinion for 1 normal DP from graph (Fig. 75)

Formulas

$$P_t = P_n \cos\psi \quad (1) \qquad d = \frac{n}{P_t} \quad (2) \qquad d_o = d + \frac{2 + K_h}{P_n} \quad (3)$$

EXAMPLE. *Given:* 12 teeth, 32 normal DP 20-degree normal pressure angle, and 18-degree helix angle.

$$P_t = 32 \times 0.95106 = 30.4339 \quad (1) \qquad K_h = 0.388 \text{ (from graph, Fig. 75)}$$

$$d = \frac{12}{30.4339} = 0.3943 \quad (2) \qquad d_o = 0.3943 + \frac{2 + 0.388}{32} = 0.468 \quad (3)$$

When an enlarged helical pinion is used, either the mating gear must be reduced in diameter or the center distance must be increased to correspond with the enlargement, as in spur gears.

INSPECTION AND TOLERANCES OF FINE-PITCH GEARS. AGMA Standard 236.01 covers the inspection and tolerances of fine-pitch gears. This standard was developed to meet the diverse applications of fine-pitch gears and safeguard the interests of quality control. Fine-pitch gears lend themselves readily and economically to inspection methods in which measurements are made under conditions closely approaching those of their operation. The gear is rotated in intimate contact with a master, both mounted on a variable center-distance fixture. The displacements or variations in center distance are measured or charted by suitable means, giving a composite check. (See Fig. 76.)

Quantity specifications are made on the basis of the results of the composite check, which do not involve backlash since backlash does not directly affect the accuracy of the gear operation and may be produced or eliminated in the mountings. A choice of backlash to suit the particular application is provided in this standard by giving each class group several ranges of backlash.

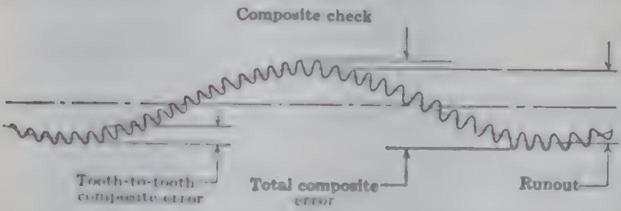

FIG. 76. Displacement variation with fine pitch gears. (AGMA Standard 236.02)

Tolerances for Commercial Fine-pitch Gears

Class	Total Composite Error, in.	Tooth-to-tooth Composite Error, in.
Commercial 1	.006	.002
Commercial 2	.004	.0015
Commercial 3	.002	.001

Tolerances for Precision Fine-pitch Gears

Class	Total Composite Error, in.	Tooth-to-tooth Composite Error, in.
Precision 1	.001	.0004
Precision 2	.0005	.0003
Precision 3	.00025 *	.0002

* This possibly would be the result of selection and segregation.

Backlash is specified by a letter suffix to the class number, such as Commercial 1B or Precision 3C.

Backlash for Different Classes of Gears

Diametral Pitch	Backlash, in.
Class A	
20 to 45	.004 to .006
46 to 70	.003 to .005
71 to 90	.002 to .0035
Class B	
20 to 60	.002 to .004
61 to 120	.0015 to .003
121 and finer	.001 to .002
Class C	
20 to 60	.001 to .002
61 to 120	.0007 to .0015
121 and finer	.0005 to .001
Class D	
No measurable backlash at any pitch.	

FINE PITCH WORM GEARING (AGMA Standard 374.01) covers eight axial worm pitches (p_x):

0.030 in.
0.040 in.
0.050 in.
0.065 in.
0.080 in.
0.100 in.
0.130 in.
0.160 in.

and fifteen lead angles (λ):

0.5 degree
1.0 degree
1.5 degrees
2.0 degrees
3.0 degrees
4.0 degrees
5.0 degrees
7.0 degrees
9.0 degrees
11.0 degrees
14.0 degrees
17.0 degrees
21.0 degrees
25.0 degrees
30.0 degrees

Worm pitch diameter (d) is calculated from the equation

$$d = \frac{l}{\pi \tan \lambda} = \frac{n p_x}{\pi \tan \lambda}$$

where l is the lead and n is the number of threads in the worm. Minimum recommended worm pitch diameter is 0.250 in., and the maximum is 2.000 in. Values of d are given in Table 35.

Worm gear pitch diameter (D) is calculated from the equation

$$D = \frac{Np}{\pi}$$

where N is the number of teeth in the worm gear and p is the circular pitch of the worm gear. Pitch relations are expressed by the equation:

$$p_n = p_x \cos \lambda = p \cos \chi$$

where p_n = normal circular pitch of worm and worm gear and χ = helix angle of worm gear. If the worm and worm gear shafts are at right angles, $\lambda = \chi$, and $p_x = p$.

Tooth Proportions. Pressure angle in the normal plane (ϕ_n) is approximately 20 degrees and the tooth proportions are as follows (see also Table 36):

Addendum $a = 0.3183 p_n$
Whole depth $h_t = 0.7003 p_n + 0.002$ in.
Working depth $h_k = 0.6366 p_n$
Clearance $c = h_t - h_k$
Tooth thickness $t = 0.5 p_n$

Backlash in fine-pitch worm gearing is produced by thinning the worm threads by a suitable amount. The worm gear is cut so that its tooth thickness and space width are equal at the standard pitch diameter.

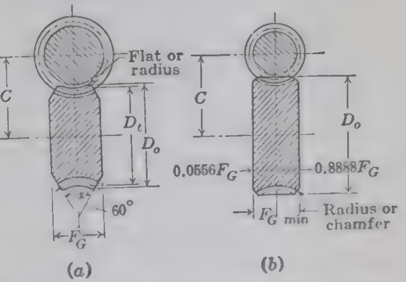
Worm Dimensions. Outside diameter of the worm (d_o) is

$$d_o = d + 2a$$

and safe minimum length of threaded portion (F_W) is

$$F_W = \sqrt{D_o^2 - D^2}$$

Worm Gear Dimensions. Two forms of worm gear blanks are used: a throated blank (for power drives), and a nonthroated blank (for transmission of motion). These are illustrated in Fig. 77.



(a) (b)

FIG. 77. Fine pitch worm gears: (a) throated gear; (b) nonthroated gear. Type a is suitable for power drives, type b for transmission of motion.

For the throated blank (Fig. 77a) the recommended dimensions are:

Outside diameter $D_o = 2C - 0.891d + 1.782a$
Face width $F_G = 0.57735 d_o$
Throat diameter $D_t = D + 2a$

where C = center distance = $\frac{1}{2}(d + D)$.

For the nonthroated blank (Fig. 77b) the recommended dimensions are:

Outside diameter $D_o = 2C - d + 2a$
Minimum face width $F_{G\,\min} = 1.125\sqrt{(d_o + 2c)^2 - (d - 4a)^2}$

Other proportions are shown in Fig. 77.

(Continued on p. 14-61)

Table 35. Pitch Diameters of Fine-pitch Worms

(This table gives the pitch diameter for each combination of lead and lead angle, together with the number of threads for a particular lead and diameter.)

Manufacture. The standard recognizes that worm profiles depend on method of manufacture, and depart from the calculated shape when production methods differ, even for the same worm. It is emphasized that manufacturing information concerning the work must be furnished when ordering gear cutting tools in order to obtain gears which are conjugate to worms. The standard includes a table of profile deviations and pressure angle changes covering the entire range of the standard.

11. MATERIALS USED IN GEARING

Materials, as such, are covered extensively in Sections 2, 3, 4, and 5 of this handbook. The problem of gearing with highly stressed surfaces and tooth structures should impress the reader with the necessity of using good-quality materials in gear design.

In the AGMA recommended practices, steels softer than 180 Brinell are not listed since good practice has been to run them with harder mates so that work hardening in service brings their "gear qualities" up close to those listed for 180 Brinell.

Referring to Fig. 50, we note that differences in hardness between the pinion (smaller member) and the gear are arbitrarily given. As has been mentioned throughout this chapter, some values are selected from experience, and this particular hardness relationship is one of them. Where exceptionally high ratios are encountered, such as in ball mill, rod mill, and kiln drives, the suggestion has been made that differing degrees in hardness might be used. In such cases the K_r factor is based (Fig. 78) on the hardness of the gear material, and a modifying factor, W_H (Fig. 79), is applied in arriving at wear-capacity ratings.

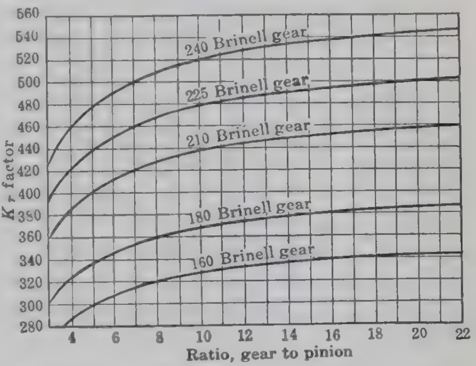

FIG. 78. Factor K_r for open large reduction gearing.

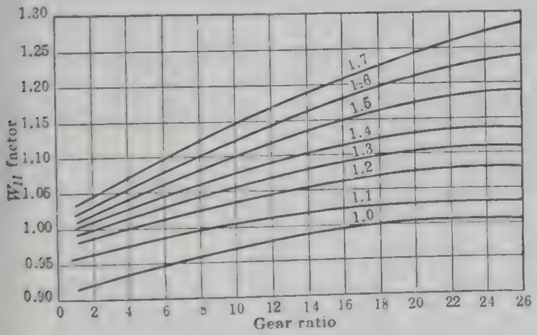

FIG. 79. Variation of W_H factor according to ratio of pinion Brinell hardness to gear hardness.

The importance of high-strength materials coupled with the awareness of load distribution has caused the gear designer to explore many treatments that promise the best compromise to these often troublesome factors. As a result, flame hardening, nitriding, shot peening of stressed areas, burnishing or cold working, and many other processes are being employed in the gear-manufacturing industry.

AGMA recommended practices for materials are covered in their Standard 241.01 for steels and 242.02 for cast iron.

12. LUBRICATION OF GEARING

The lubrication of enclosed and open gearing requires special attention, since the areas of contact on gear teeth (regardless of type of construction) are relatively small, and the unit pressures developed in transmitted rated loads are relatively high. It is, therefore, essential to use a lubricant of sufficient film strength to withstand the localized pressure during the short period of contact.

Unfortunately, lubricating-oil specifications have not been developed to the point where they can be referred to as such. As a consequence, certain general characteristics to be looked for in selecting a gear lubricant are summarized in the following paragraphs.

Lubricating oils for geared mechanisms should be high grade, high quality, and well refined. They must not be corrosive to gear materials, and should be neutral in reaction and free from grit and abrasives. In addition, gear lubricants should have good defoaming properties, and, where high operating temperatures are encountered, their resistance to oxidation should be checked.

Straight mineral types of lubricants are usually recommended for all types of gears except those of the worm and hypoid construction. For worm gearing, additions of 3 to 10% acidless tallow or animal fats to straight mineral lubricant is usually found to be desirable. Hypoid gears require special attention, for which acceptable grades of extreme pressure lubricants can be selected.

Tables 37, 38, 39, 40, and 41 are taken from the AGMA Standard Specification 250.01, covering lubrication of enclosed and open gearing.

Table 37. Viscosity Range for Various AGMA Lubricants

AGMA Lubricant Number	Viscosity Range, SUV seconds At 100 F	At 210 F
1	180 to 240	....
2	280 to 360	....
3	490 to 700	....
4	700 to 1000	....
5	....	80 to 105
6	....	105 to 125
7	....	125 to 150
7 Comp.*	....	125 to 150
8	....	150 to 190
8 Comp.*	....	150 to 190
9	....	350 to 550
10	....	900 to 1200
11	....	1800 to 2500

* The oils marked "Comp." are compounded with 3 to 10% of acidless tallow or other suitable animal fat. Oils 9, 10, and 11 should be of a tacky adhesive nature so that they will adhere well to the tooth surfaces.

Table 38. Recommended Lubricants for Enclosed Units of All Types except Worm Gears

Type of Units	Size of Units	Ambient Temperature, °F 0–40 Use AGMA No.	41–100 Use AGMA No.	101–150 Use AGMA No.
Parallel shaft units	Low-speed, centers up to 20 in.	2	4	5
	Low-speed, centers over 20 in.	3	5	6
Planetary gear units	OD of housing up to 16 in.	2	3	4
	OD of housing over 16 in.	3	4	5
Gear motors	All sizes	2	4	5
Spiral or straight bevel gear units	Cone distance up to 12 in.	2	4	5
	Cone distance over 12 in.	3	5	6
High-speed units	All sizes	1	2	3

Table 39. Recommended Lubricants for Enclosed Worm-gear Units Only

Service and Worm Speed	Ambient Temperature, °F 0–40 Use AGMA No.	41–90 Use AGMA No.	91–120 Use AGMA No.
Intermittent operation—all worm speeds *	5	5	7 Comp.
Continuous operation—worm speeds below 600 rpm	7 Comp. diluted †	8 Comp.	8 Comp.
Continuous operation—worm speeds 600 rpm and over	7 Comp. diluted †	7 Comp.	7 Comp.

* Where period of operation is insufficient to produce any appreciable rise in oil bath temperature.

† Diluted AGMA 7 comp. oil should be diluted with a lighter oil, preferably not exceeding 500 sec viscosity at 100 F, until the desired fluidity is obtained. The lubricant used for dilution should be of the same basic crude as that of the recommended oil. The lubricant supplier should be consulted if there is any doubt.

Table 40. Recommended Lubricants for Open Gearing of All Types except Worm Gears

Method	Ambient Temperature, °F 0–40 Use AGMA No.	41–100 Use AGMA No.	101–150 Use AGMA No.
Slush pans	3	5	6
Hot—by brush or paddle	10	10	11
Cold—by brush or paddle	6	8	10
Hand-oiled	4	6	8

Table 41. Recommended Lubricants for Open Worm Gears Only

Method	Ambient Temperature, °F 0–40 Use AGMA No.	41–100 Use AGMA No.	101–150 Use AGMA No.
Cold or hot—by brush or paddle	6	8	..

Lubrication Maintenance. (*a*) Ambient temperature, which is here defined as the temperature of the air in the vicinity of the gears or gear unit, has considerable bearing on the viscosity of oil to be used. In general, the viscosity of mineral oil varies inversely with the temperature. This makes it desirable to use an oil of heavier grade at high ambient temperatures than would be used for the same application operating in a low ambient temperature. Also, for low temperatures, an oil must be selected which has a pour point lower than the minimum temperature expected for the application.

(*b*) Sludge in gear units may be caused by metallic particles ground off the gears, by dust and dirt, and by the presence of moisture or chemical fumes. Therefore, every precaution should be taken to prevent water and foreign particles from entering the gear case.

(*c*) Open gears operating in dusty atmospheres should be periodically cleaned with kerosene or other suitable solvent. The dirt and grit adhering to them can seriously damage the tooth surfaces if it continuously passes through the mesh.

ACKNOWLEDGMENTS. Much of the material on conventional worm gearing, spiral gearing, and elliptical gearing has been reproduced from Professor Earle Buckingham's material used in the previous edition.

The data on bevel gearing are taken from material supplied by Mr. F. L. Knowles of the Gleason Works, who is chairman of the Bevel Gear Committee of the AGMA.

Louis D. Martin, gear engineer of Eastman Kodak and chairman of the Fine-Pitch Committee of the AGMA, assisted in culling out of AGMA data, pertinent information for this section.

The AGMA was most cooperative in locating and supplying information on industry standards.

Dean McCurdy, a senior at the University of Washington, prepared the majority of the new illustrations used in this section.

SHAFTS, KEYS, AND SPLINES

1. SHAFTING

STANDARD SIZES for finished shafting are given in Table 1. Diameters tabulated under Transmission Shafting agree with the commercial sizes of bearings, couplings, etc., and are usually supplied in the full stock lengths of 16, 20, or 24 ft, as desired. The series designated Machinery Shafting, which includes a larger number of sizes in the same range of diameter, is intended for machine construction, etc., and is generally desired in shorter lengths. Three types of shafting are contemplated within the standard: (1) cold drawn, (2) turned and polished, and (3) turned, ground, and polished.

SHAFT HANGERS are made of cast iron or pressed steel in a variety of forms by different manufacturers. Typical designs are illustrated in Figs. 1, 2, and 3. The frames will accommodate various types of bearings such as ball-and-socket bearings, ball or roller bearings, ring or capillary oiling bearings, and plain babbitted bearings. Hangers usually have adjusting screws to adjust the bearing in a vertical plane, to conform to the desired shaft height.

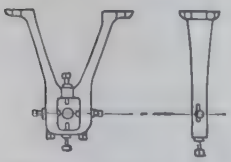

FIG. 1. Shaft hanger.

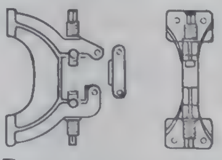

FIG. 2. Adjustable ball-and-socket post hanger.

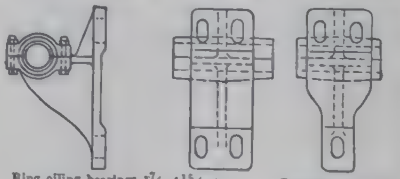

Ring oiling bearings 1 7/16–4 15/16 in. Babbitted bearings over 3 in.

Babbitted bearings up to 3 in. shaft

FIG. 3. Rigid post bearing.

DISTANCE BETWEEN BEARINGS. The spacing of hangers for line shafting depends on the size of shaft and the points at which load is applied. The following figures represent average practice with pulleys placed near the bearings.

Shaft size, in.	15/16-1 7/16	1 11/16-2 3/16	2 7/16-2 15/16	3 7/16-3 15/16	4 7/16-4 15/16
Distance between bearings, ft	6	8	10	12	14

Linear Deflection. For continuous line shafting, it is considered good practice to limit deflection to a maximum of 0.01 in. per foot of length. The weight of bare shafting, in pounds, is $W = 2.6d^2L$. When the shaft is fully loaded with pulleys as is usual in practice, with an allowance of 40 lb per inch of width for the vertical pull of belts, the load in pounds will be about $W = 13d^2L$. With a modulus of transverse elasticity of 26,000,000, the following equations determine length between bearings to avoid excessive deflection.

For bare shafting, $L = \sqrt[3]{873d^2} \qquad d = \sqrt{L^3/873}$ (1)

For shafting carrying pulleys, etc., $L = \sqrt[3]{175d^2} \qquad d = \sqrt{L^3/175}$ (2)

In the foregoing equations L = maximum distance in feet between bearings for continuous shafting subjected to bending stress only; d = diameter of shafting in inches.

FLEXIBLE SHAFTING consists of an inner core of built-up wire coils, brazed or soldered into end fittings, surrounded by a protecting casing.

2. SHAFT DESIGN

HORSEPOWER TRANSMITTED BY SHAFTING. Formulas relating shaft diameter, shearing stress, torque, and horsepower are given in Section 8, Article 12. In practice, the following factors of safety are generally used for transmission shafting: for head shafts, 15; for line shafts carrying pulleys, 10; for small, short shafts, countershafts, etc., 7. For steel shafting of 60,000 psi tensile strength, the allowable stress with the foregoing factors would be 4,000, 6,000, and 8,500 psi, respectively, whence the diameters of shafts would be

Head shafts $d = \sqrt[3]{80\ \text{hp}/N}$ (3)

Line shafts $d = \sqrt[3]{53.5\ \text{hp}/N}$ (4)

Short shafts $d = \sqrt[3]{38\ \text{hp}/N}$ (5)

TORSIONAL DEFLECTION. For the same horsepower, torsional stress is inversely proportional to the speed of rotation, but bending stress will not be reduced in the same ratio. Therefore, it is not practicable to write an equation covering the whole problem which is sufficiently simple for practical use. The following rules, however, are correct within the range of velocities that usually occur under shop conditions. For continuous shafting, so proportioned as to deflect not more than 0.01 in. per ft of length, allowance being made for the weakening effect of keyseats,

For bare shafts, $d = \sqrt[3]{50\ \text{hp}/N} \qquad L = \sqrt[3]{720d^2}$ (6)

For shafts carrying pulleys, etc., $d = \sqrt[3]{70\ \text{hp}/N} \qquad L = \sqrt[3]{140d^2}$ (7)

CODE FOR DESIGN OF TRANSMISSION SHAFTING. The American Standards Association has issued a code for the design of transmission shafting, in which all commonly used theories are discussed and a rational procedure for the design of shafts under all conditions of loading is developed. The following notes are adapted from the code.

Notation. A = area of cross section, square inches; α = ratio of maximum to average intensity of stress, resulting from axial loading only; D = outside diameter of shaft, inches; d = inside diameter of hollow shaft, inches; E = modulus of elasticity, approximately 30,000,000; F = axial tensile or compressive load, pounds; $K = d/D$ = ratio of inside diameter to outside diameter of hollow shafts; K_m = shock and fatigue factor to be applied to the computed bending moment; K_t = shock and fatigue factor to be applied to the computed torsional moment; k = radius of gyration of transverse cross section of the shaft, inches; l = length of shaft between centers of supports, inches; M = maximum bending moment, inch-pounds; N = revolutions per minute; P = maximum power transmitted by the shaft, horsepower; S = maximum flexural stress, either tension or compression, pounds per square inch, 16,000 for commercial shafting without allowance for keyways, 12,000 with allowance for keyways;* S_s = maximum shearing stress in shaft, pounds per square inch, 8000 for commercial shafting without allowance for keyways, 6000 with allowance for keyways;* T = maximum torsional moment, inch-pounds; V = transverse shear, pounds; W = transverse load supported by shaft, pounds.

---

* S may be taken as 60% of the elastic limit in tension, but not more than 36% of the ultimate tensile strength of steel purchased under definite physical specifications. Similar values for S_s are 30% of elastic limit and 18% of ultimate strength.

SOLID SHAFTS. The formulas recommended differ from the formulas heretofore in general use in that they introduce factors K_m and K_t for shock and fatigue. These factors vary with the nature of the load. Values are given in Table 2.

Table 2. Shock and Fatigue Factors for Shafts

	K_m	K_t
Stationary shafts		
Gradually applied loads	1.0	1.0
Suddenly applied loads	1.5–2.0	1.5–2.0
Rotating shafts		
Gradually applied or steady loads	1.5	1.0
Suddenly applied loads, minor shocks only	1.5–2.0	1.0–1.5
Suddenly applied loads, heavy shocks	2.0–3.0	1.5–3.0

Shafts in Pure Torsion.

$$K_tT = 0.1963S_sD^3 \tag{8}$$

$$D = \sqrt[3]{321{,}000K_tP/S_sN} \tag{9}$$

Shafts Subjected to Bending.

$$D = \sqrt[3]{32K_mM/\pi S} \tag{10}$$

Shafts Subjected to Combined Torsion and Bending.

$$D = \sqrt[3]{(16/\pi S_s)\sqrt{(K_mM)^2 + (K_tT)^2}} \tag{11}$$

If the diameter to transmit a given horsepower is desired, it may be found by substituting for the term $(K_tT)^2$ in eq. 11 its value in terms of horsepower, as follows:

$$(K_tT)^2 = \left(\frac{396{,}000K_tP}{2\pi N}\right)^2 \tag{12}$$

Shafts Subjected to Torsion, Flexure, and Axial Loading. This is the general case, and all other shaft formulas may be derived from it by the omission of the factors that do not apply to the case under consideration.

$$D = \sqrt[3]{\frac{16}{\pi S_s}\sqrt{\left(K_mM + \frac{\alpha FD(1 + K^2)}{8}\right)^2 + (K_tT)^2} \times \frac{1}{\sqrt[3]{1 - K^4}}} \tag{13}$$

To determine the diameter of a shaft in terms of horsepower transmitted, substitute in equation 13 the value of $(K_tT)^2$ as found by equation 12.

Shafts in Bending over Short Spans with Heavy Transverse Shear.

$$D = \sqrt{16V/3\pi S_s} \tag{14}$$

Shafts Subjected to Combined Torsion and Heavy Transverse Shear.

$$S_s = (16T/\pi D^3) + (16V/3\pi D^2) \tag{15}$$

Diagrams for Solution of Shafting Problems. All equations given above, except equations 14 and 15, can best be solved by the diagrams in Figs. 4 and 5. In these diagrams, the heavy arcs represent standard transmission shafting sizes, and the lighter arcs the standard machinery shafting sizes. The scale of abscissas represents values of K_mM; the scale of ordinates at the right represents values of K_tT; the scale of ordinates at the left represents the values of K_tP, where P = horsepower at 100 rpm. The diagrams are applicable to steady, fluctuating, reversing, and gradually or suddenly applied loads, with or without minor or heavy shocks, provided that correct values of K_m and K_t are used. They are not applicable to shafts in bending over short spans with heavy transverse shear, or to shafts subjected to combined torsion and heavy transverse shear.

The diagrams are based on a maximum permissible shearing stress of 6000 psi but can be used for other stresses by multiplying the shaft diameter found from the diagram by an appropriate factor as follows:

Shearing stress, psi	4000	5000	6000	7000	8000	9000
Factor	1.14	1.06	1.00	0.95	0.91	0.87

EXAMPLE 1. Required: the size of shaft to withstand a maximum bending moment M of 9350 lb, and a maximum torsional stress T of 9600 lb, the allowable unit shearing stress being 8000 psi, and the load suddenly applied with minor shock. From Table 2, values of K_m and K_t may be taken as 1.5 and 1.25, respectively. Then $K_mM = 1.5 \times 9350 = 13{,}975$, and $K_tT = 9600 \times 1.25 = 12{,}000$. In Fig. 4, the intersection of $K_mM = 13{,}975$, and of $K_tT = 12{,}000$ lies on the arc representing a shaft 2 1/2 in. in diameter, with a unit stress of S_s of 6000 psi. Since the allowable unit torsional stress in the present case is 8000 psi, the correct diameter for the conditions given is found by applying the factor for the higher stress. $2.5 \times 0.91 = 2.275$. The next higher standard size of shaft is 2 5/16 in.

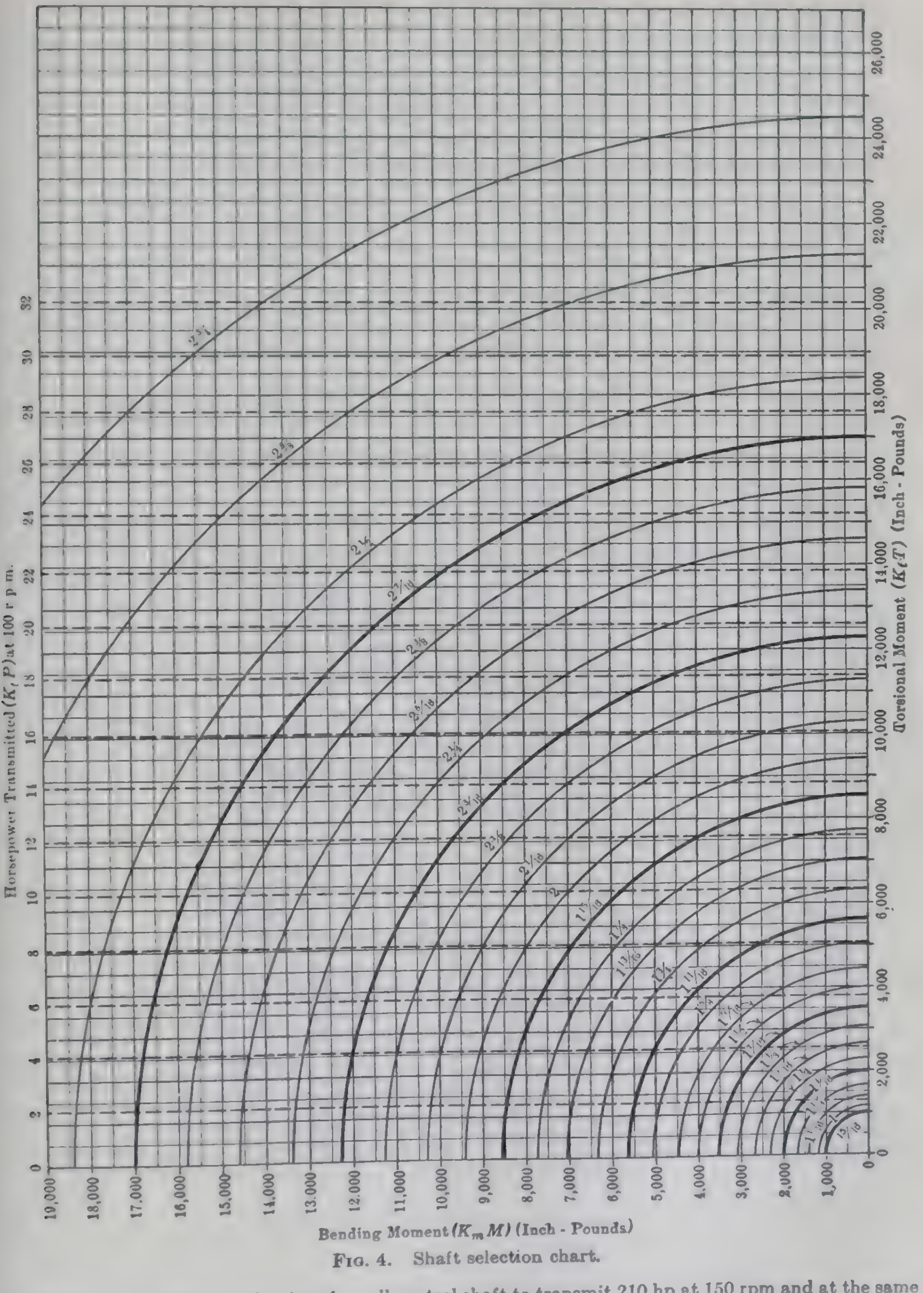

FIG. 4. Shaft selection chart.

EXAMPLE 2. Required: the size of an alloy steel shaft to transmit 210 hp at 150 rpm and at the same time sustain a bending moment of 90,000 in.-lb. The unit allowable shearing stress may be taken as 9000 psi. At 150 rpm, 210 hp is equivalent to 210 × (100/150) = 140 hp at 100 rpm. The intersection of 140 hp and K_mM = 90,000 in Fig. 5 shows that a shaft 4 3/4 in. in diameter would be required at a unit shearing stress of 6000 psi. Applying the factor 0.87 for the higher unit stress, 4.75 × 0.87 = 4.1325 in. The next larger standard shaft is 4 1/4 in. in diameter.

EXAMPLE 3. Required: the size of a nonrotating shaft to support a steady load of 4000 lb, the supports being spaced 3 ft apart. From the equation for simple beams (see p. 8-12), $M = Pl/4$ = 4000 × (3 × 12)/4 = 48,000 in.-lb. From Table 2, $K_m = 1$, and K_mM = 48,000. Since there is no rotation, $T = 0$, and $K_tT = 0$. In Fig. 5, on the abscissa of $K_tT = 0$, at a value of K_mM = 48,000, the nearest size of shaft that will be suitable at a unit shearing stress of 6000 psi is 3 1/2 in.

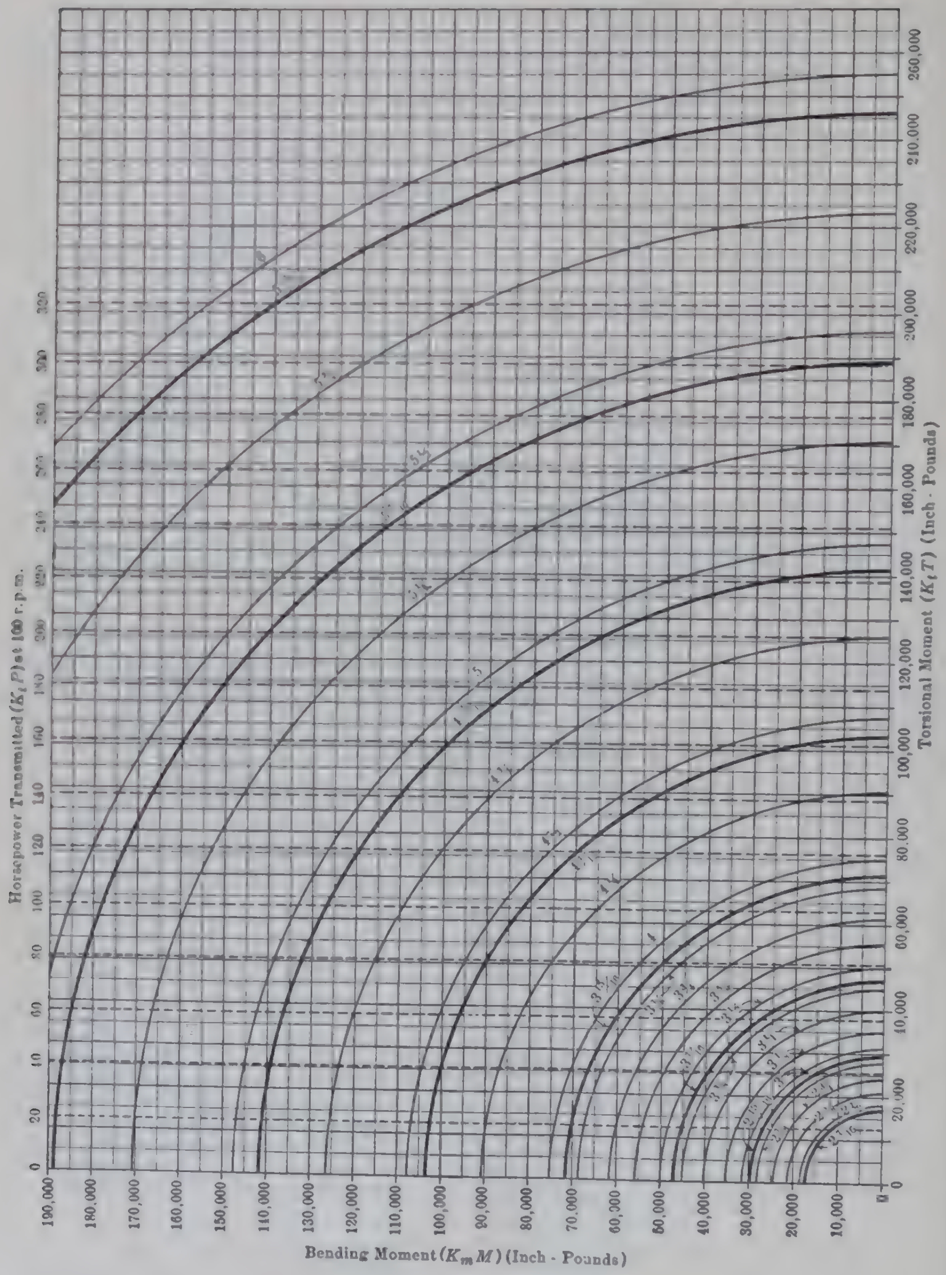

Fig. 5. Shaft selection chart.

HOLLOW SHAFTS. All the foregoing equations are applicable to hollow shafts, when multiplied by a factor equivalent to $(1/\sqrt[3]{1-K^4})$, in which $K = d/D$, that is, the ratio of the inside and outside diameters. Values of $(1/\sqrt[3]{1-K^4})$ are as follows:

K	0.95	0.90	0.85	0.80	0.75	0.70	0.65	0.60	0.55	0.50
$\sqrt[3]{1-K^4}$	0.57	0.70	0.78	0.84	0.88	0.91	0.93	0.95	0.97	0.98
$1/\sqrt[3]{1-K^4}$	1.75	1.43	1.28	1.19	1.14	1.10	1.07	1.05	1.03	1.02

The procedure is to determine the diameter of a solid shaft for the given conditions and then to multiply the diameter so found by the factor corresponding to the desired value of d/D.

EXAMPLE 4. Determine the size of a hollow shaft to be used under the conditions given in Example 1, assuming the value of K as 0.70. As determined in Example 1, the diameter of a solid shaft required would be 2.275 in. The factor for $K = 0.70$ is 1.10. Therefore, the outside diameter of an equivalent hollow shaft would be $2.275 \times 1.10 = 2.502$ in. The inside diameter would be $2.502 \times 0.70 = 1.75$ in.

SHAFTS UNDER AXIAL LOADING. The maximum intensity of stress resulting from a force F applied axially is $S = \alpha F/A$, where α = ratio of maximum to average intensity of stress resulting from the axial load only, and A = cross-sectional area of the shaft, square inches. If the shaft is rigidly supported at short intervals and virtually acts as a column under compressive loads, $\alpha = 1$. Under all tensile axial loads, also, α is 1. If the shaft is not rigidly supported, it acts as a long column, and α should be computed by one of the long-column formulas. Values of α, for ratios of l/k up to 115, computed according to the formula

$$\alpha = 1/[1 - 0.0044(l/k)] \tag{16}$$

are given below. For ratios of l/k greater than 115, use Euler's equation (see p. 8-22).

Ratio, l/k	0	25	50	75	100	115
α	1.00	1.12	1.28	1.49	1.78	2.02

The value of α so determined then should be used in equation 13 to determine the size of shaft required.

SHAFTS UNDER ALTERNATING STRESS. Shafts subjected to torsion and bending encounter reversal of stress at each revolution and should be calculated by means of equation 11. The values to be ascribed to the shock and fatigue factors, K_t and K_m, which take into account the stress reversals, depend on the conditions under which the shaft operates. No general statement can be made concerning the values to be used, since the shock factor, in particular, depends on the resiliency of the shaft system as a whole. For complete stress reversal, K_t and K_m should be 1.5.

CRITICAL SPEEDS. Shafts carrying masses such as pulleys, flywheels, gears, etc., may be subject to transverse or torsional vibrations. These vibrations may become critical when the speed of rotation is equal to a natural frequency of free vibration. Torsional vibrations may be critical at several speeds, owing to exciting harmonics in the transmitted torque. For methods of calculation, see Section 9, Article 5.

3. KEYS

Keys are used to prevent relative movement of rotating members and the shafts or spindles on which they are mounted. They are of various forms, depending on the class of service in which they are to be used.

SUNK KEYS are made in various forms, as square, flat, tapered, etc. Square and flat keys preferably should be fitted on all four sides. See Figs. 6, 7, 8, and 9.

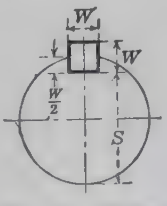

FIG. 6. Square plain parallel stock key. See Table 3.

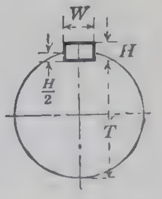

FIG. 7. Flat parallel stock key. See Table 4.

A key fitting tightly on top and bottom of the keyway drives partly by friction. If fitted only on the sides of the keyway, it exerts a prying action on the hub and shaft and is subjected to severe bending and shearing stresses.

Taper keys (Fig. 9) are tapered on the upper surface only, i.e., on the surface projecting into the hub. A corresponding taper is cut in the keyway in the hub. When the key is driven, hub and shaft are drawn together on the side opposite the key. A frictional resistance thus is established which tends to prevent axial movement of the hub on the shaft.

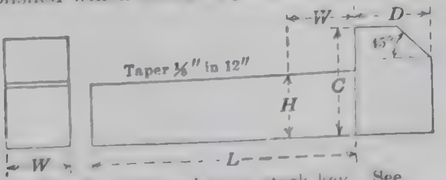

FIG. 8. Gib-head taper stock key. See Table 5.

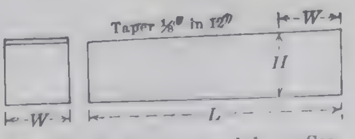

FIG. 9. Plain taper stock key. See Table 6.

If the key is more tightly fitted at one end than at the other, or if the bore of the hub is tapering, the hub may be so drawn up that its axis is at an angle to the axis of the shaft. The Woodruff key (Fig. 10) adjusts itself to taper in the hub and thus avoids misalignment of shaft and hub.

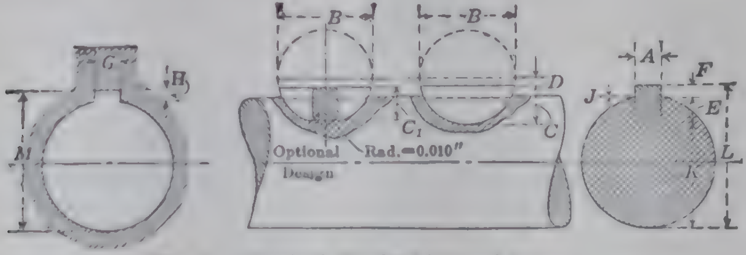

Fig. 10. Standard Woodruff key and keyseat.

FORMS OF KEYS. Standard Stock Keys. The American Standards Association has established standard sizes for plain parallel and taper stock keys, square and flat, and square and flat taper gib-head stock keys. Dimensions of these keys are given in Tables 3, 4, 5, and 6. These keys are intended to be cut from cold-finished stock and used without further machining, the dimensions and tolerances having been fixed with this consideration in mind.

Depth of Keyseats. In addition to giving the key dimensions, Tables 3 and 4 give the distance from the bottom of the keyseat to the opposite side of the shaft, in order to facilitate gaging for the correct depth of keyseat when machining. This dimension is calculated on the basis of the keyseat being cut to a depth equal to one-half of the height of the key, this depth being measured at the side of the keyseat. For shaft and key dimensions other than those in the tables, S and T may be calculated from the following equations:

$$S = d - A - \frac{W}{2} \tag{17}$$

and

$$T = d - A - \frac{H}{2} \tag{18}$$

where $A = (d - \sqrt{d^2 - W^2})/2$, which is equal to the height of the arc projecting above

* Tolerance on W is −0.0020 in. for shafts 1/2 to 1 3/4 in., inclusive; −0.0025 in. for shafts 1 13/16 to 3 1/4 in., inclusive, −0.0030 in. for shafts 3 3/8 to 6 in., inclusive.

the intersection of the side of the keyway with the circumference of the shaft and d = shaft diameter.

The Woodruff key is extensively used in machine tools, and in the automotive industry. The keyslot is cut in the shaft with a milling cutter. The hub is forced on the shaft over the key. Dimensions of standard Woodruff keys are given in Table 7. The dimensions of J, K, L, and M, Fig. 10, which are not given in Table 7, can be computed by means of the following formulas, in which d = diameter of the shaft, other factors being as shown in Fig. 10.

Versed sine,

$$J = {}^1/_2 d - \sqrt{(d^2 - A^2)/4} \tag{19}$$

Bottom of keyseat to opposite side of shaft,

$$K = (d - J - E) \tag{20}$$

Top of key to opposite side of shaft,

$$L = (F + E + K) \tag{21}$$

Bottom of keyway to opposite side of bore,

$$M = (d - J + H) \tag{22}$$

Keys and Keyways for Arbors and Milling Cutters. Table 8 gives dimensions and tolerances of keys and keyways for milling cutters and arbors, as developed by the American Standards Association.

The Kennedy Key. The Kennedy key, largely used in rolling mill work, is shown in Fig. 12. In these keys, $w = t = {}^1/_4 D$. They are tapered $^1/_8$ in. per ft on top, and the sides are a neat fit. The keys are so set in the shaft that diagonals through them intersect at the axis of the shaft. If, in assembling, the hub is to be slid along the shaft for a considerable distance, the hub is bored for a press fit and then is rebored eccentrically about $^1/_{64} D$ off center. The keyways are cut in the eccentric side. General practice is to use single keys for diameters up to and including 6 in. where the torque is constant and the power transmitted always in one direction. For shafts above 6 in. in diameter, double keys should be used, and, if the torque is intermittent and in alternate directions, double keys should be used down to shaft diameters of 4 in.

* This height of the key is measured at the distance *W*, equal to the width of the key, from the large end.

† 4 1/2 in. length instead of 4 3/8 in.

Figure 13 shows a key devised by Wilfred Lewis, which is similar in principle to the Kennedy key and which is used for lighter service, as machine tool work. It is subject to compression only, but it has the disadvantage of being expensive and difficult to fit.

The Barth Key. The key shown in Fig. 14 was devised by Carl G. Barth to combine the advantages of the Lewis key with those of the ordinary rectangular key. The Barth key is rectangular, with one-half of both sides beveled at 45 degrees. The key does not need to fit tightly, as pressure tends to drive it into its seat. There is no tendency to turn it, and the only stress to which it is subject is compression. This key has been used in many cases as a feather to replace rectangular feather keys which have given trouble. It has found wide application as a feather key in drill sockets and drill shanks, reamers, etc., which are commonly driven with a tang.

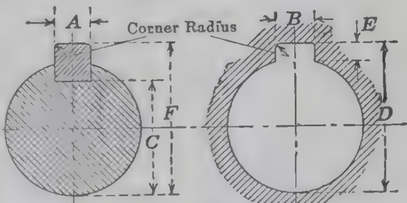

FIG. 11. Keys and keyways for arbors and milling cutters.

The Nordberg Key. The Nordberg Manufacturing Co. has adopted for the ends of shafts the round keys shown in Fig. 15. The advantages of this key are: there is no tendency toward deformation; they are a driven fit in the direction of the shear; they are always in true shear and are cheaper than the square key. In manufacturing, a hole *A* is drilled in the joint, and next a hole *B* as large as the size of the keyway will admit is drilled in the shaft in order to avoid the tendency of the drill used for drilling the keyway to size to crowd into the soft cast iron. The taper is 1/16 in. per ft., measured on the diameter.

LIGHT KEYS. Where only small amounts of power are to be transmitted and it is impracticable or inadvisable to use a sunk key, a key driving on a flat or a saddle key may be used. These two types of key drive mainly by friction.

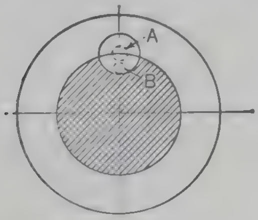

Fig. 15. Nordberg key.

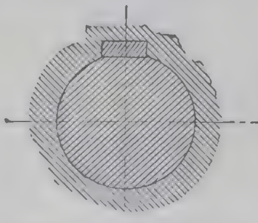

Fig. 16. Key on flat.

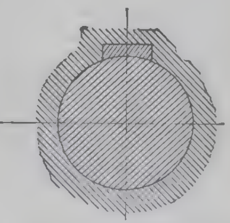

Fig. 17. Saddle key.

Key on Flat. If a small flat be milled or filed on the shaft, a flat key with a slight taper may be driven into a keyway in the hub opposite the flat on the shaft. See Fig. 16. This type of key is suitable for transmission of light powers and has the advantage of ease of assembling. Such a key should not be subjected to sudden changes in torque, as it then may slip on the shaft and seriously damage it.

Saddle Key. The saddle key, Fig. 17, depends entirely on friction to prevent motion of the hub relative to the shaft. The key is driven into a keyway in the hub, and the face of the key bearing on the shaft is made with a radius somewhat smaller than the radius of the shaft. The key should have a slight taper.

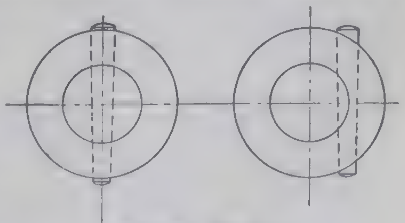

Fig. 18. Pin keys.

Pin keys are adapted to transmit power with light loads. Figure 18 shows two methods of using taper pins as keys. Table 9 gives the dimensions of standard taper pins.

Groov-Pins are parallel pins having a shallow axial split extending along part or all of the length. This split is widened so as to enlarge the effective diameter of the pin.

Table 9. Dimensions of Taper Pins

Taper 1/4 in. in 12 in. All dimensions in inches. See Fig. 19.

When driven into a drilled hole the pin holds tight by virtue of the pressure required to close the split. (Groov-Pin Corp., Union City, N. J.)

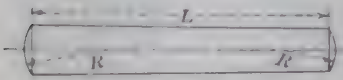

Fig. 19. Taper pin.

FEATHER KEYS are used when the hub must slide axially along the shaft but at the same time rotate with it. The feather key is a sunk key. It may be either dovetailed into the shaft or fastened in place by screws. Figure 20 shows various forms. If the key is required to slide with the hub, the construction shown in Fig. 20c may be used. Instead of feather keys, spline shafts now are largely used.

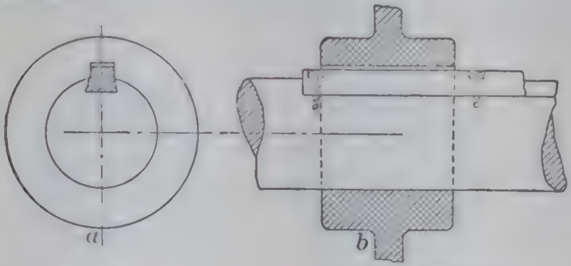

Fig. 20. Feather keys.

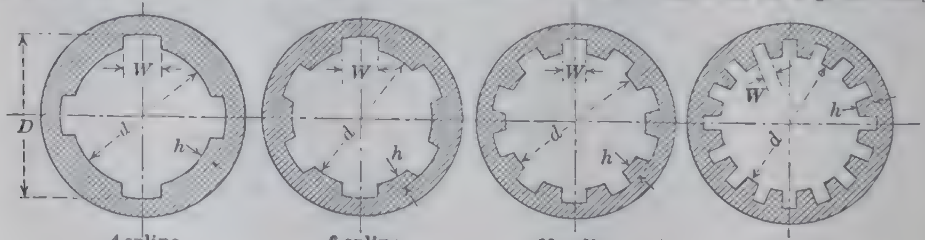
4. SPLINES AND SERRATIONS

Instead of keys, spline shafts may be used for the transmission of power from a shaft to a hub or vice versa. Two types of splines have been standardized—square and involute.

SQUARE SPLINES are employed in multiple-spline fittings having 4, 6, 10, or 16 splines (see Fig. 21). They have become established as basic standards for a great many



4-spline 6-spline 10-spline 16-spline

Fig. 21. Spline fittings.

applications in the automotive, machine tool, and other industries. Standardized by the SAE, their proportions are intended to apply only to soft broached holes, the shaft dimensions depending on the shape and material of the parts, their heat treatment, methods of machining, etc., to give the required fit. Dimensions of these standardized fittings are given in Table 10. Nominal values of *D* range from $^3/_4$ in. to 1 $^3/_4$ in. by increments of $^1/_8$ in., from 1 $^3/_4$ in. to 2 $^1/_2$ in. by increments of $^1/_4$ in., and from 2 $^1/_2$ to 6 in. by increments of $^1/_2$ in. Three types of fits provide for (*A*) permanent fit, (*B*) sliding when not under load, and (*C*) sliding under load.

Torque capacity of spline fittings may be determined by the formula

$$T = 1000NrhL$$

where N = number of splines; r = mean radial distance from center of hole to center of spline = $(D + d)/4$; h = depth of spline; and L = length of spline bearing surface; all in inches. This gives torque in inch-pounds and is based on a pressure of 1000 psi on the sides of the spline.

Table 10. Formulas for Spline Proportions

(SAE Standard. See Fig. 21.)

No. of Splines	*W* For All Fits	Permanent Fit		To Slide When Not under Load		To Slide under Load	
		h	*d*	*h*	*d*	*h*	*d*
Four	.241*D*	.075*D*	.850*D*	.125*D*	.750*D*	....	....
Six	.250*D*	.050*D*	.900*D*	.075*D*	.850*D*	.100*D*	.800*D*
Ten	.156*D*	.045*D*	.910*D*	.070*D*	.860*D*	.095*D*	.810*D*
Sixteen	.098*D*	.045*D*	.910*D*	.070*D*	.860*D*	.095*D*	.810*D*

For *D* and *d*, tolerance allowed of −0.001 in. for shafts $^3/_4$ to 1 $^3/_4$ in., inclusive; −0.002 for shafts 2 to 3 in., inclusive; −0.003 in. for shafts 3 $^1/_2$ to 6 in., inclusive, for 4-, 6-, and 10-spline fittings; tolerance of −0.003 in. allowed for all sizes of 16-spline fittings.

For *W*, tolerance allowed of −0.002 in. for shafts $^3/_4$ to 1 $^3/_4$ in., inclusive; −0.003 in. for shafts 2 to 6 in., inclusive, for 4-, 6-, and 10-spline fittings; tolerance of −0.003 allowed for all sizes of 16-spline fittings.

INVOLUTE SPLINES. American Standard. Involute splines are multiple keys in the general form of internal and external involute gear teeth, used to prevent relative rotation of cylindrically fitted machine parts. Involute splines can be machined by the same methods and equipment as those customarily used in the production of gears. The nomenclature agrees as nearly as possible with the standard gear nomenclature adopted by the American Gear Manufacturers Association and the American Standards Association, except that the words "root diameter," "outside diameter," and "inside diameter" have been changed to "major diameter" and "minor diameter" to avoid confusion. The pressure angle is 30 degrees, splines are based on diametral pitch, involute form, having addendum and dedendum each equal to 0.5/*DP*, and circular tooth thickness of 1.5708/*DP*. (For nomenclature, see Fig. 22.)

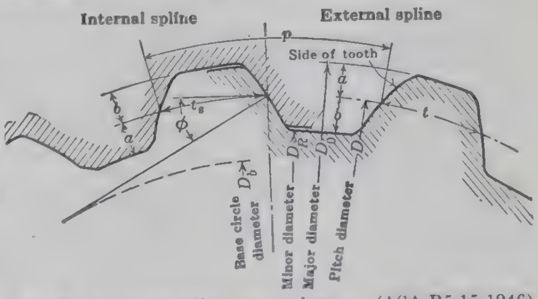


Fig. 22. Involute spline nomenclature. (ASA B5.15-1946)

Because of the almost universal practice of broaching the internal spline, it has been held to basic dimensions and the external spline dimensions varied to control the fit. This corresponds to the general practice of fitting to a reamed or drilled hole, because of the fixed condition of the finishing tools and gages.

Tooth size is designated by two numbers such as $^8/_{16}$, where the first number (8 in this case) is the diametral pitch (*DP*) used in all calculations. The following pitches are included in the standard: 1/2, 2.5/5, 3/6, 4/8, 5/10, 6/12, 8/16, 10/20, 12/24, 16/32, 20/40, 24/48, 32/64, 40/80, and 48/96. Table 11 gives formulas for the leading dimensions of splines, which may have numbers of teeth ranging from 6 to 50. Clearances and tolerances being determined by manufacturing experience and not by direct proportions, space does not permit inclusion here of all the manufacturing dimensions and inspection data for all sizes. These may be found in the complete standard, ASA B5.15-1946, *Involute Splines*.

Table 11. Basic Formulas for Involute Spline Proportions

(See Fig. 22)

Dimension	Symbol	Formula
Circular pitch	p	$\frac{3.1416}{DP}$
Circular tooth thickness	t	$\frac{1.5708}{DP}$
Pitch diameter	D	$\frac{N}{DP}$
Base circle diameter	D_B	$0.8660D$
Addendum, dedendum	a, b	$\frac{0.500}{DP}$
Major diameter	D_O	$\frac{N+1}{DP}$
Minor diameter	D_R	$\frac{N-1}{DP}$

Types of Fits. There are three methods of fitting spline members together: *major diameter*, where fit is controlled by varying the major diameter of the external splines; *sides of the teeth*, where fit is controlled by varying tooth thickness (it is customary to use this fit on full fillet-type splines), and *minor diameter*, where fit is controlled by varying the minor diameter of the internal splines (requires special tooling).

The three methods are each divided into three classes: sliding, close, and press fits. Sliding fits must have clearance at all points; close fits must be close at one point; and press fits must involve an interference at only one point.

Length of Splines. For carrying any load, or to obtain stability, it is seldom necessary to have a spline longer than its pitch diameter. If the strength of the shaft in shear is equated to that of the spline in shear, allowing for only 25% effective tooth contact, the following equations result for spline length:

With a solid shaft of diameter D,

$$L = \frac{D_R^3}{D^2}$$

With a hollow shaft of external diameter D and internal diameter D_I,

$$L = \frac{D_R^4 - D_I^4}{D^2 D_R}$$

INVOLUTE SERRATIONS. SAE Standard. Involute serrations are multiple keys in the general form of internal and external involute gear teeth, used for permanent fits between shafts and parts mounted on them. The standard provides a uniform, easily fabricated set of serrations that can be made by several manufacturing processes. The nomenclature agrees with that of the ASA standard for involute splines (see preceding paragraphs and Fig. 23).

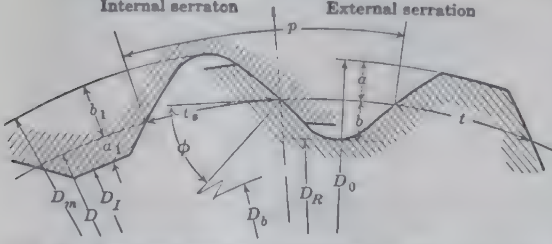

FIG. 23. Involute serration nomenclature. (Reproduced by permission from the *SAE Handbook*, 1949 edition)

The pressure angle is 45 degrees, and the serrations are based on involute form, as generated with a straight-sided hob of the form included in the standard. Serrations may be parallel or tapered (recommended taper, 0.750 in. per ft included angle, measured on major diameter).

The scope of the standard includes the pitches given in Table 12; the first number in the pitch designation (e.g., 24 in 24/48) is the DP used in all calculations. For each pitch, the range of numbers of teeth is also given.

Table 12

Pitch	Range of N	Pitch	Range of N	Pitch	Range of N
10/20	6–100	32/64	21–65	64/128	21–34
16/32	6–100	40/80	32–55	80/160	14–27
24/48	6–100	48/96	24–46	128/256	11–24

Formulas for the leading dimensions are given in Table 13 (see Fig. 23 for nomenclature).

Table 13. Formulas for Involute Serration Proportions

(See Fig. 23)

Dimension	Symbol	Formula
Circular pitch	p	$\frac{3.1416}{DP}$
Circular tooth thickness	t	$\frac{1.3708}{DP}$
Circular space width	t_s	$\frac{1.7708}{DP}$
Pitch diameter	D	$\frac{N}{DP}$
Base circle diameter	D_b	$0.7071D$
External serration		
Addendum	a	$\frac{0.500}{DP}$
Dedendum	b	$\frac{0.500}{DP}$
Major diameter	D_O	$\frac{N+1}{DP}$
Minor diameter	D_R	$\frac{N-1}{DP}$
Internal serration		
Addendum	a_I	$\frac{0.300}{DP}$
Dedendum	b_I	$\frac{0.700}{DP}$
Major diameter	D_m	$\frac{N+1.40}{DP}$
Minor diameter	D_I	$\frac{N-0.60}{DP}$

Fits and Tolerances. Three classes of fits are designated in the standard: loose (A); close (B); and press (C). The dimensions for the internal serrations are held the same on all fits, the external serration being varied to obtain the desired fit. Modifications are made to obtain equal-strength teeth in both members and at the same time retain even steps of major diameter in well-known fractions. The standard also specifies tolerances for space width and tooth circular thickness and should be consulted for all manufacturing and inspection data.

COUPLINGS

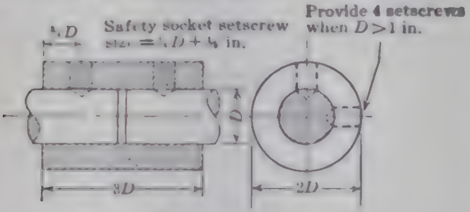
By A. F. Gagne, Jr.

Couplings are used to join lengths of shafting, which must often be sectionalized for practicability and economy in manufacture and shipping or for purposes of ready installation. This applies to long transmission shafting, to shafts of separately built driving and driven machine units, and, on occasion, to short shafts within machines. Couplings of special types are also used to join shafts at angles, to prevent the transmission of overloads, to secure controlled slippage, and to engage or disengage power at will. Couplings of the last type are commonly known as clutches and are discussed in the succeeding chapter.

5. RIGID COUPLINGS

Rigid couplings are used to make a solid connection between shafts. They are of various types.

THE SLEEVE COUPLING forms a simple, low-cost, rigid joint between two shafts. Also known as a "box" or "muff" coupling, it consists of a substantial sleeve fitted snugly over the shafts and secured with keys, taper pins, or setscrews. Figure 1 gives approximate proportions of commercial setscrew couplings, suitable for light duty. Sleeve couplings are commonly applied from the very smallest sizes up to 2 in., although a heavy-duty "OK" coupling has been developed by SKF for large marine drives which dispenses with keys and uses a patented high-pressure oil injection technique to expand the sleeve for movement on or off. The threaded solid coupling, another heavy-duty type, is often used on the vertical drive shaft of deep well pumps in capacities up to 1000 hp at 1200 rpm.



¾D
Safety socket setscrew size = ¼D + ⅛ in.

Fig. 1. Set-screw sleeve coupling.

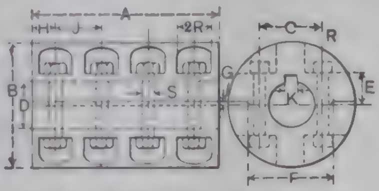

Fig. 2. Clamp shaft coupling. See Table 1.

THE CLAMP SHAFT COUPLING is essentially a split and bolted sleeve coupling, proportioned to clamp firmly on the shafts. This construction permits removal without interfering with adjoining bearings or requiring separation of the shafts. These couplings are made for the heaviest duty, and because of convenience and low relative cost are often used at moderate speeds in sizes up to 5 in. When the coupling must carry a tensile load across the shafts, split ring keys can be inserted in matching grooves machined on the shafts and in the coupling halves. *Halsey's Handbook* gives the typical dimensions shown in Fig. 2 and Table 1 for the standard cast-iron design.

FLANGE COUPLINGS are commonly used in permanent installations for heavy loads and large sizes and particularly for vertical drives, as agitators. Although somewhat larger in diameter, they are shorter and, in typical designs, 20% lighter than other heavy-duty types. Their dimensions have not been standardized by the various manufacturers, but Fig. 3 and Table 2 are representative. Alignment is obtained by piloting the end of one shaft one-eighth diameter into the opposing flange as shown or, at extra cost, by making the flange halves male and female, a shallow rabbet on one flange fitting into a recess in the other flange near its periphery. For best results, the flanges should be shrunk on the shafts and finish machined. Uniform bolt load distribution is obtained by reaming both flanges together for a body fit on the bolts.

Flange couplings may be disconnected when required, provided the pilot shaft end is lubricated and the flanges are separated to prevent rubbing. A removable split plate is useful in securing separation without disturbing the fit of flange to shaft.

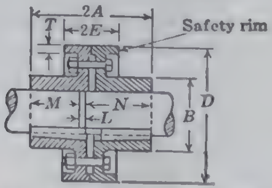

Fig. 3. Flange coupling. See Table 2.

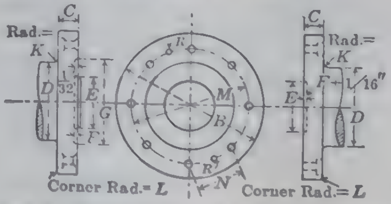

Fig. 4. Integrally forged hydroelectric unit coupling. See Table 3.

HYDROELECTRIC UNIT COUPLINGS. A complete series of integrally forged, small-diameter, heavy-duty flange couplings has been standardized by the ASA, as indicated in Fig. 4 and Table 3. Minimum weight has been achieved by reducing flange torsional and bending strength to match that of the shaft.

40	68	10	8	24	5/8	39	3 1/2	3/8	18	5 1/4	57 3/4	10.03	5	8
48	80	12	9 1/2	28	5/8	47	4	3/8	18	6 1/4	67 1/2	11.72	6	8

Note. Rabbets are turned and coupling bolt holes reamed for standard wring fits. Safety flanges can be provided over the bolts. Three to four jack screws are provided, ranging in size from 3/4″-10NC, for the smallest coupling to 1 1/2″-8N, for the largest.

The values in the table are based on the following approximate proportions:

Flange diameter, $B = 1.75D$

Flange thickness, $C = 0.25D$, if subject to bending

Flange thickness, $C = 0.20D$, if not subject to bending

Rabbet diameter, $E = 0.60D$

Permissible bolt stress = 1.20 × shaft stress

KEYLESS COMPRESSION COUPLINGS. The common flange design consists of a slotted, double-taper sleeve, clamped on the shafts by bolted taper flanges as in Fig. 5 and Table 4. Jackscrews are used to disassemble. This design offers the advantages of adjustability and low installed cost, since no machining of the shafts is required. It is not suitable for heavy or shock loads.

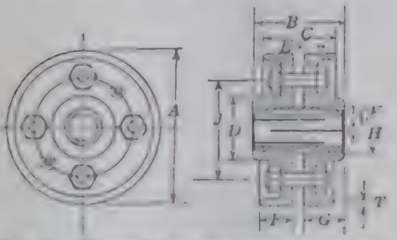

Fig. 5. Flanged keyless compression coupling. See Table 4.

CURVIC COUPLINGS maintain firm alignment in built-up crankshafts such as are used on large aircraft engines. The construction involves the machining of accurately matching crown gear teeth into the two mating faces of the hubs to be joined. The assembly is ordinarily held together by a central bolt but can be separated for clutching action if mounted on a pilot shaft. An adaptation is seen in Fig. 22.

Table 4. Dimensions of Flanged Keyless Compression Couplings

(Dodge Manufacturing Corp., Mishawaka, Ind.)

Shaft Size, in.	Dimensions, in. (see Fig. 5)										Bolts		Average Weight, lb

Note: Slotted reducing thimbles furnished for either shaft as required. Intermediate sizes available.

* Maximum flange diameter, plus 0.004 in., minus 0.000 in. This is 0.012 in. smaller than maximum sleeve diameter. Taper is 3/4 in. per ft, diametral.

6. FLEXIBLE COUPLINGS

When three or more bearings are located closely in line on one shaft or on shafts of two machine units connected by a rigid coupling, there is, except for special constructions, a considerable likelihood of bearing trouble and loss of power. These result from misalignment, which also produces fatigue-inducing alternations of tensile and compressive stress in the shaft. The misalignment is typically caused by inadvertent installation errors or by subsequent wear, thermal expansion, machine deflection under load, foundation settling, or loosening of bolts.

The ill effects of such misalignment are commonly avoided by inserting a flexible coupling between shafts, which also lessens alignment labor. A well-chosen flexible coupling will operate with negligible maintenance cost and power absorption and will introduce no harmful vibrations or resonances into the system.

In general, flexibility is attained in one or more of the following three ways:

1. Loosely fitted hard parts. Such couplings are suitable for low speeds and light loads only.
2. Hard parts arranged for lubricated sliding action and made with close fits.
3. Flexible or resilient parts, which do not require lubrication but may place some load on the bearings if misaligned.

In applying flexible couplings, it must be borne in mind that most types are of very limited flexibility and accordingly will suffer damage or rapid wear if due care is not taken at installation to assure an alignment well within the limits recommended by the manufacturer. In general, good installation practice on ordinary couplings has been considered a lateral alignment within 0.002 to 0.004 in. for high-speed drives such as turbines, and within 0.01 in. for low-speed drives.

There are various methods of securing alignment accuracy. One of the best aids is a straight edge laid across the shafts or coupling halves at several points around the periphery and checked with feeler gages. At the same time, sufficient clearance must be allowed between flanges to accommodate all motor and machine end-play, as cramping of the flexible coupling action and destructive hammering will otherwise occur. During the service which follows, alignment and clearance should be checked periodically and corrected as required to stay within the manufacturer's recommendation.

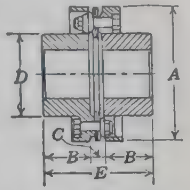

Fig. 6. Single-engagement Thomas flexible coupling. See Table 5.

In view of the large variety of flexible couplings commercially available, they are classified as follows according to the amount and degree of freedom offered.

LONGITUDINAL FLEXIBILITY is usually necessary to accommodate thermal expansion and motor end play. Together with other essential characteristics, it is found in most flexible coupling designs.

ANGULAR FLEXIBILITY. Figure 6 and Table 5 illustrate a single-engagement Thomas coupling, used effectively between two bearings of a combination of three bearings in line (Fig. 7); for example, a fan motor and a self-aligning outboard bearing. The laminated metal ring permits a maximum angular deflection of 1/2 degree and a longitudinal displacement of 1% of the shaft diameter yet provides full support for rotor weight. The coupling is quiet at high speeds and does not require lubrication. Its torsional rigidity adapts it well to cam and other closely timed drives.

Table 5. Dimensions and Capacities of Laminated Steel Ring Flexible Coupling
(Type ST—The Thomas Flexible Coupling Co., Warren, Pa.)

Maximum				Dimensions, in. (see Fig. 6)				
Bore, in.	Rpm	Horsepower at 100 rpm *	*P*,† lb	*A*	*B*	*C*	*D*	*E*
1 5/8	5800	0.8	150	4 19/32	1 3/4	13/32	2 3/4	3 29/32
2	4650	1.5	225	5 3/4	2 1/8	7/16	3 1/2	4 11/16

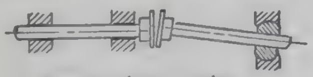
8	1200	177	7700	22 3/8	7 3/4	1 7/8	13 5/8	17 3/8

Note: Other types available include flange adapter for flywheels and double engagement for greater flexibility, in sizes from 1/16 to 13 in. Intermediate sizes available.

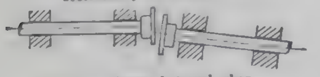
* With full lateral load. Double capacity without lateral load.

† *P* is the lateral load or pull on coupling in pounds.

The double-engagement style, consisting of two flexible rings bolted compactly to a central spider, is available when lateral flexibility is indicated, as discussed below.



Three bearings: angular flexibility necessary



Four bearings: lateral plus angular flexibility necessary

Fig. 7. Flexibility requirements of different bearing combinations.

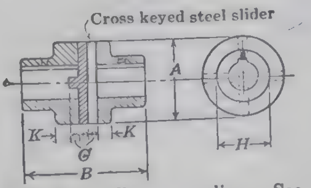


Fig. 8. Oldham coupling. See Table 6.

LATERAL, OR PARALLEL, FLEXIBILITY is required in addition to angular flexibility when two pairs of bearings are connected. (See Fig. 7.) On lightly loaded shafts under 1 in. in diameter and operating at speeds under 100 rpm, adequate lateral and angular flexibility can be secured at low cost by a loose-fitting *tongue and groove joint* in the shaft ends or by a standard *jaw clutch* made with considerable clearance.

The well-known *Oldham coupling*, Fig. 8 and Table 6, eliminates the need for large clearances and the resultant noisy backlash by providing a double-tongued central slider fitting between two flanges slotted at right angles to each other. It allows considerable end play and lateral misalignment (up to 5% of shaft diameter under favorable condi-

Table 6. Dimensions and Capacities of Oldham Coupling

(Palmer-Bee Co., Detroit, Mich.)

tions† plus angular misalignment of 1 degree. It is often used for speeds under 100 rpm and for heavy loads up to the full shaft capacity, as in connecting a gear reducer to the driven machine. Lubrication is required, and the coupling must be protected from grit and dirt. Each shaft should be supported by a bearing near the coupling.

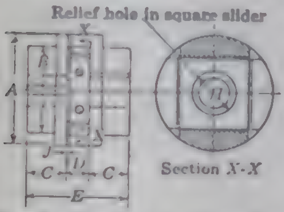

Fig. 9. C-flange coupling. See Table 7.

Figure 9 and Table 7 illustrate a modern development of the Oldham coupling adapted by its large and well-lubricated bearing area to general-purpose work at speeds up to those of standard motors. Torque is transmitted by C-shaped jaw flanges through a square, sliding center member which is surfaced with replaceable bearing strips lubricated from a reservoir within. This coupling will compensate for misalignments as high as 10% lateral and 3-degree angular without inducing reactionary stresses in the shafts and bearings, but for maximum life it should be accurately aligned at installation, like most other couplings. When the coupling is abused by excessive misalignment such as might appear after some time, all wear is taken by the easily replaceable bearing strips.

Table 7. Dimensions and Capacities of C-Flange Coupling

(American Flexible Coupling Co., Erie, Pa.)

* For Series B, nonmetallic bearing strips on hard chrome-plated jaws. One-half for Series A, with nonmetallic bearing strips on plain jaws. Double capacity for Series C, using metallic, nonferrous bearing strips on hard chrome-plated jaws.

† **Increase for high angular misalignments or greater end-play allowance.**

TORSIONAL RESILIENCE. In addition to misalignment compensation, a small degree of torsional flexibility is often desirable in a high-speed flexible coupling in order to lessen noise and to prevent transmission of starting and running shocks to the motor or gear reducer. This is provided in various amounts by a wide variety of couplings based on the fundamental construction of two flanges connected by resilient spring or nonmetallic elements. The Ajax style, Fig. 10 and Table 8, cushions by means of steel pins bolted alternately to one flange and sliding in self-lubricated bronze bushings, rubber-cushioned in the opposite flange. The manufacturer recommends limiting misalignment to 1/2 degree angular and 0.5% lateral. Torsional deflection under full load is 1/4 degree. The construction permits free axial movement to accommodate motor end play and is especially

suited to damping shock and momentary overload. It also affords electrical insulation, thus preventing such dangers as electrolysis in direct motor-driven pumps.

A frequently seen variation made by a number of manufacturers provides alternate pins or lugs on the face of each flange, fitting loosely in a leather or composition disk so as to place this material in compression (Fig. 11, Table 9). The driving and driven members should be aligned carefully for best results. The nonmetallic material is sometimes used in the form of replaceable cushions or plugs in pockets, a construction permitting brake lining for shock loads at low speeds and high temperatures; leather for sustained loads; and armored rubber for high flexibility, high speeds, and chemicals or wet conditions. In case of cushion failure, such couplings continue to drive but give audible warning.

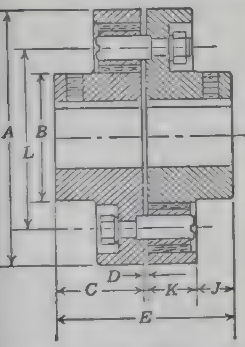

FIG. 10. Coupling with rubber-bushed studs. See Table 8.

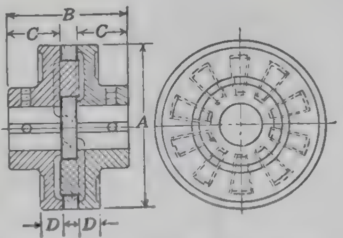

FIG. 11. Leather disk coupling. See Table 9.

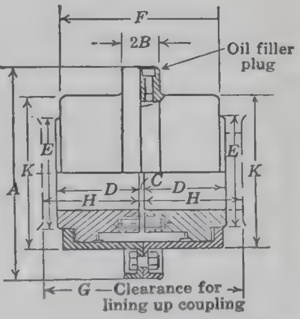

FIG. 12. Double-engagement gear-type coupling. See Table 10.

In still other types, an *endless leather belt* is interwoven between flange pins, or tangential *leather links* carry the load across flange bolts. A more modern construction uses a composition fabric disk bolted in alternation to flanges on each side, similar to Fig. 6.

Note: Larger sizes available to 70,000 hp at 100 rpm, also intermediate sizes.

* Misalignment values shown can be accommodated by sliding of the teeth on the grid member without strain on the coupling shafts. However, operation at maximum values will accelerate wear on teeth and grid member; hence, couplings should be closely aligned for long life and minimum maintenance.

† Clearance *M* required to allow installation or removal of grid member.

‡ Includes one hub and half the total grid, grease, and cover weight.

A moderate-cost, heavy-duty, *gear-type coupling,* made by a number of manufacturers, consists of a spur gear on one hub free to slide axially in a mating internal gear on the other hub. The gear teeth on the hub are usually crowned and made with sufficient clearance to provide a 3/4-degree free rocking action for axial shaft misalignment. Ordinarily, lateral misalignment must also be accommodated, and the double-engagement style is specified as in Fig. 12 and Table 10. In extreme cases, two single-engagement types may be separated by a short floating shaft. Lubrication is provided by a dust- and grit-proof casing filled with heavy oil distributed to all teeth by centrifugal force. The large area of lubricated surface also cushions shock and permits quiet high-speed operation.

These couplings are commonly used for paper mills, jordans, and rolling mills, but they are being specified for an increasing number of general-purpose jobs. Being all metal, they are suitable for service at elevated temperatures. They are built for horizontal operation ordinarily, but suitable supports and lubricant retainers can be provided for vertical operation. The largest standard size is 30 in. (120,000 hp at 200 rpm maximum speed, Fast's Coupling Dept. of Koppers Co., Inc.).

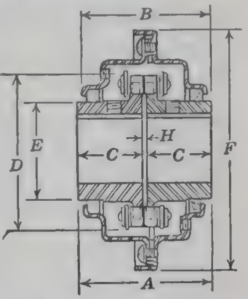

FIG. 13. Roller chain flexible coupling. See Table 12.

The chain coupling, Fig. 13 and Table 12, provides limited cushioning through slight spring action. It is assembled from two sprockets connected by roller or silent chain and is preferably covered with a protective and grease-retaining shield. Because lateral flexibility derives from small clearances between sprockets and chain, the coupling requires careful alignment. A relatively new type, the Baldwin-Duckworth, minimizes backlash and provides up to 6 degrees of angular flexibility through the use of spherical rollers on one or both sprockets. Silent chain couplings (Morse) are made for capacities up to 1800 hp at 300 rpm, maximum. Principal advantages are low cost and ready disconnection.

Table 12. Dimensions and Capacities of Roller Chain Flexible Coupling

(Link-Belt Co., Philadelphia, Pa.)

Maximum			Dimensions, in. (see Fig. 13)							Weight, lb
Bore, in.	Rpm	Horse-power at 100 rpm	*A*	*B*	*C*	*D*	*E*	*F*	*H*

12	900	186	12 5/8	6 1/2	6 1/8	19 15/16	15 1/16	21 3/8	1/8	316

Note: One-degree maximum permissible angular misalignment. Intermediate sizes available.

HIGH TORSIONAL FLEXIBILITY is sometimes necessary to isolate extreme shock loads or vibration. Together with good lateral and angular flexibility, this is provided in fractional horse-power sizes (3/16- to 1-in. shafts) by the inexpensive bonded-rubber flexible couplings made by the Lord Manufacturing Co. Full-load torsional deflection is 15 degrees.

The Airflex coupling, made in sizes ranging from 1 1/4 to 17 in. (4700 hp at 100 rpm) consists of an inflated rubber tube fitting inside the driven member. With a strong damping action and a full-load twist angle of 1 degree, it is well suited to high-speed Diesel engine or reciprocating pump and compressor drives. Permissible lateral misalignment is 1/16 in.; angular misalignment is 1 degree. The coupling may be disconnected by deflating.

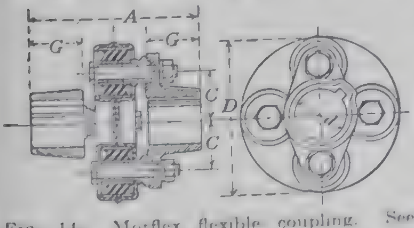

FIG. 14. Morflex flexible coupling. See Table 13.

The *Morse Morflex coupling,* Fig. 14, secures high flexibility by means of a floating center spider carrying four heavy neoprene cushions bolted to alternate flanges. Full-load twist averages 3 degrees, and maximum permissible angular deflection is 5 degrees. Lateral misalignments less than 1% of the shaft diameter are carried without excessive bearing

Table 13. Dimensions and Capacities of Morflex Flexible Couplings

(Morse Chain Co., Ithaca, N. Y.)

Maximum			Dimensions in inches (see Fig. 14)				Stiffness Factors				Wr^2, lb-in.^{2}	Weight lbs.

Note: Intermediate and fractional horsepower sizes available.

loading, as seen in Table 13, which gives stiffness factors in addition to dimensions of selected sizes. The Morflex coupling requires no lubrication and may be operated in oily or grimy conditions at temperatures up to 180 F; hence it is well suited for portable construction and oil-field equipment.

Because of high torsional deflection, destructive resonance can occur on pulsing drives, and the ratio of *critical speeds* must be checked as with any coupling having a full load deflection over 1 degree. The manufacturer recommends that the natural frequency of the coupling and rotating part system be made less than 40% or more than 200% of the exciting frequency. This can be done by selecting a larger coupling to raise the natural system frequency or by using two couplings in tandem to lower it. Auxiliary damping can be provided where the range of natural frequencies is too great. Morse also manufactures a high-damping *Radial coupling* having a full-load torsional deflection of only 1 degree, which may be a better choice for installations requiring less misalignment compensation. Sizes range from 1 3/8 to 8 in. (262 hp at 100 rpm).

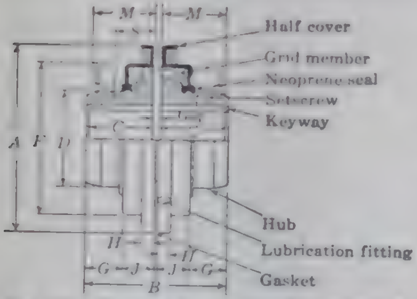

FIG. 15. Steelflex coupling. See Table 11.

There are several all-metal high-flex couplings particularly useful for heavy duty or higher temperatures. *Flexible shafting* is excellent for small sizes, although in larger sizes it is necessary to provide flange-type couplings with some form of spring connection. The *Falk Steelflex coupling*, Fig. 15, comprises a flat steel spring wound in the form of a grid over specially shaped grooves cut into each hub. A housing retains grease and protects the coupling from grit. Table 11 gives dimensions and permissible misalignment values for standard couplings. Because of its nonlinear spring rate and grease filling, this coupling has good damping characteristics and is useful in avoiding certain types of tooth chatter. It should be checked for critical speeds, however.

DOUBLE ENGAGEMENT (FLOATING-SHAFT) COUPLINGS. As previously indicated, when an unusual amount of flexibility is required in all directions, for example by the very flexible frame found in most vehicles, two high-flex couplings can be connected in tandem. These must be types that give full lateral support to the intermediate shaft or element. The Oldham as such would be quite impractical. Again, provided that floating shaft length and speed are not so great as to produce whipping, the double coupling construction is often used to eliminate intermediate bearings when the driving and driven machines are separated by several feet, or by a wall.

SERVICE FACTORS. In order to assure adequate coupling life on pulsating loads, it is necessary to increase the size of the coupling over that determined on a basis of maximum shaft size or rated horsepower capacity. The service factors given in Table 14 are representative of values given in most catalogs and are to be used in the following formula, which allows for fatigue and overheating at higher speeds.

$$\text{Nominal horsepower capacity at 100 rpm} = (\text{Service factor})\ (\text{required horsepower}) \left(\frac{100}{\text{required rpm}}\right)^{3/4}$$

Note: The manufacturer should be consulted regarding critical or unusual conditions.

Table 14. Service Factors

Type of Load	Electric Motor or Steam Turbine	Steam Engine or 4-, 6-, or 8-Cylinder Gasoline Engine	Gas or Oil Engine
Uniform (fans, centrifugal pumps, agitators, generators, line shafts)	1	1 1/2	2
Moderate shock (beaters, grinders, hoists, ball mills, reciprocating pumps or compressors with 3 or more cylinders)	1 1/2	2	2 1/2
Heavy shock (boat propellers, 1- to 2-cylinder compressors and pumps, crushers, hammer and rolling mills)	2	2 1/2	3

Note: Multiply by 1.5 for operation 24 hr per day.

SELECTION FACTORS. The following factors should be checked in addition to the usual considerations of cost, size, weight, and limiting speed for a coupling of adequate capacity:

Special requirements, as frequent disengagement, high end play, thrust or lateral support, and electrical insulation.

Torsional Stiffness or Flexibility. Check on advantages of vibration isolation versus possibilities of critical speeds.

Accessibility. Some couplings must be accessible for inspection, lubrication, or replacement of perishable parts.

Service Conditions. Will the coupling operate satisfactorily when wet, oily, dirty, hot, or cold, as the case may be? Is it suited to shock or reversing loads, and is there a sufficient margin of flexibility to provide for probable alignment drifts with time? The greater the speed, the more margin desirable.

Means of Installation. Light machinery—types with spring resistance to lateral deflection aid line-up at assembly. Heavy machinery—it should be possible to lower the machinery directly into place and then assemble the coupling halves after aligning, without further movement of the machinery.

Failure. Will the coupling give warning before failing completely?

7. UNIVERSAL JOINTS

Universal joints allow positive transmission of power at larger angles than are permissible with flexible couplings. Such joints are sometimes competitive with bevel gearing, although they differ in that the angle may be varied at will but the speed ratio must remain unity.

THE HOOKE OR CARDAN JOINT is the commonest universal joint. It is formed of two U-shaped yoke hubs joined by a cross-shaped piece with four trunnion bearings, one fitting in each yoke arm. Table 15 gives proportions of selected sizes, and Fig. 16 illustrates the *Bocorselski* construction, equivalent to the *Curtis*, in which the smaller trunnion pin fits through the larger to lock it in place. Made of alloy steel, this sturdy, compact style has been extensively used in aircraft. Various other constructions are available for particular applications, as the *Apex* rubber-booted joint or the *Mechanics* and *Blood-Brothers* sealed, heavy-duty, roller-bearing joints, made in sizes up to 50,000 ft-lb torque.

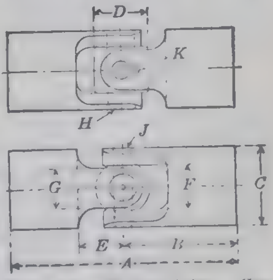

Fig. 16. Hooke joint. See Table 15.

The Hooke joint has one basic defect, a cyclic pulsation of the angular velocity of the driven shaft. The total variation is 3% at 10 degrees, 13% at 20 degrees, 29% at 30 degrees, 55% at 40 degrees, and 71% at 45 degrees. Accordingly, the working angle is kept below 15 degrees if possible, and angles over 30 degrees up to a maximum of 45 degrees are permissible only for manual or very slow speed motions.

When required, uniform angular velocity can be obtained by compensating the motion of one joint with a second; the double joint also considerably increases maximum allowable working angles. The two Hooke joints are connected by a plate or short intermediate shaft, often made telescoping as when powering table feeds on machine tools. In order

Table 15. Proportions and Capacities of Hooke Universal Joints

(Baush Machine Tool Co., Springfield, Mass.)

Maximum		Dimensions, in. (see Fig. 16)							Diameters, in.			
Bore, in.	Horsepower at 100 rpm *	*A*	*B*	*C*	*D*	*E*	*F*	*G*	*H*	*J*	*K*	Approx. Weight, lb
3/16	0.07	1 3/4	7/8	3/8	17/64	7/32	7/32	3/16	0.1065	0.0595	...	0.05
1/2	2.0	3 5/8	1 11/16	1	11/16	9/16	9/16	1/2	5/16	7/32	1/8	0.67
1	16	5 7/16	2 23/32	2	1 7/16	1 3/32	1 3/16	1 1/16	11/16	7/16	1/8	4.0
2 1/2	103	10 7/8	5 [illegible]/16	4	2 3/4	2 5/16	2 1/16	1 7/8	1 1/16	3/4	1/4	31

* Safety factor of 2; 0 to 5 degrees operating angle.

to secure perfect uniformity of motion, it is essential that the trunnion pins of the two inner yokes be assembled parallel and that the intermediate shaft make the same angle with both driving and driven shafts.

CONSTANT VELOCITY irrespective of shaft angle is also characteristic of three heavy-duty universal joints originally developed to secure a compact means of powering automotive front-drive steering axles. These joints are typically capable of a 37-degree maximum deflection and are lubricated and sealed for high-speed operation under adverse conditions. Standard sizes range from 15/16 to 2 1/2 in.

The *Bendix-Weiss joint* (Fig. 17) consists of four steel balls placed in intersecting curved races cut in the joint members, the races guiding the balls to precisely half the shaft angle. A central ball absorbs thrust. The *Rzeppa joint*, made by the Gear Grinding Co., is somewhat similar but requires a cage to control ball position. It consists of a spherical, internally grooved driving member fitting about a star-shaped driven member in the manner of a ball-and-socket joint. Six steel balls fit in the mating half-grooves in each member and transmit torque by a free rolling action. The *Tracta joint*, made by the New Process Gear Co., is essentially a double Hooke joint compacted by ingenious construction.

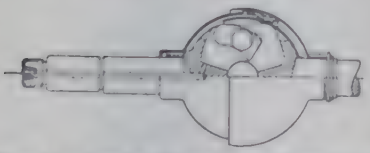

FIG. 17. Bendix-Weiss constant-velocity universal joint.

Another type of constant velocity universal joint built for low cost is typified by the *Brooks hinged joint*, in which power is transmitted between two bevel gears of alternate ball-and-socket form supported in a casing hinged on a line through the ball centers in the zone of contact. The angle between shafts may be varied from 0 to 92 degrees. The joint was originally developed for long-distance manual operation of valves, etc., but is now recommended for light power transmission at speeds up to 150 rpm. It is made in sizes from 1/2 to 2 1/2 in. An equivalent joint using rounded crown teeth is made by *Gray & Prior* and operates through an angle of 0 to 136 degrees.

8. OVERLOAD RELEASE COUPLINGS

Overload release couplings are devices which will transmit no more than a certain preset torque. They are used for protection of driving or driven machine elements in the event of a sudden stop or jam and are a valuable and inexpensive insurance against costly repairs and production outages. Basically, mechanical overload release protection is required because the momentary overload capacity of the standard motor and drive is several times that of critical machine members or of fragile articles being processed.

In general, overload protection is recommended for the following:

(1) Automatic machinery in which the motor armature inertia is a major portion of the total machine inertia, particularly if a serious breakdown could result from poor timing or a failure of any individual part or motion.

(2) Light accessory drives taking power from a heavy-duty main drive.

(3) Machinery processing or handling damageable articles, as hoppers and packaging machines.

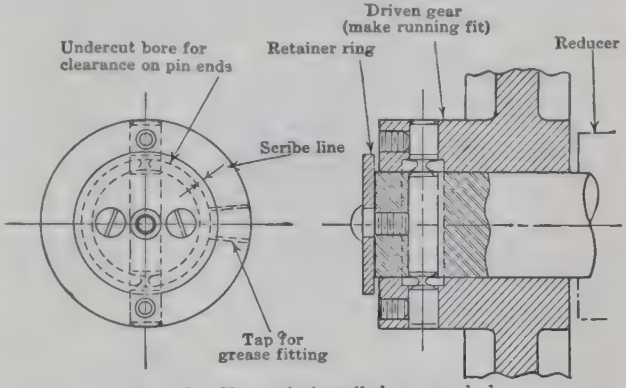
(4) Machinery subject to damage from tramp iron, oversize material, or other obstruction, as conveyors, crushers, winches, and dredge pumps.

(5) Limit releases on traverse drives for doors, machine tools, etc.

(6) Feeds and drives for valuable machine-tool cutters subject to breakage from jams, as tapping heads, milling cutters, and broaches.

Overload release type devices are also used for special purposes, including nut runners and wire or sheet windups. Various multipurpose forms are available, incorporating special features as may be required, such as cushioned or flexible coupling action, controlled slippage for easy starts and speed or tension control, and overspeed or underspeed release. Such protection is installed as near the load as possible to minimize parasitic inertia.

THE SHEAR PIN is readily applied to most drive arrangements at a minimum of cost and is reliable when properly designed. Because of fatigue, it cannot be made very sensitive, however, and replacement is a nuisance. Therefore, use should be restricted to drives subject to overloading at very infrequent intervals only, where the design breaking load can be at least double the normal running torque.



Undercut bore for clearance on pin ends
Driven gear (make running fit)
Retainer ring
Reducer
Scribe line
Tap for grease fitting

Fig. 18. Shear pin installed on gear hub.

Several important design points are illustrated in Fig. 18, which shows a noncommercial application made on a gear hub in place of a taper pin.

Proper Control of Fracture. The shear pin body is made double or triple the required diameter and the shear point or points are U-notched to suit the load. This also permits torque adjustment.

Pin Material. Should be predictable and low in notch sensitivity, although wood has been used successfully in addition to brass, bronze, mild and stainless steels, and cast iron.

Free Rotation after Fracture. Assured by providing lubrication plus grooves in the hub and shaft to clear the ends of the pin after shearing. Individual setscrews on each pin section prevent possible shifting and jamming before or after shearing.

Easy Pin Replacement. All edges and shoulders are well chamfered, and the rotating parts are scribed to aid positioning.

This design contains one possible fault: Unauthorized personnel may replace the necked-down pin with one of full diameter or even of hardened steel in order to stop breakages, even though the shear pin may be preventing serious damage. For this reason, some engineers prefer to anticipate by designing for a hardened pin of full diameter and accepting the possibility that undirected pin breakage will cause seizing.

The following formula can be used for the double-shear design of Fig. 18·

$$\text{Torque} = D \times S_s \times 0.7854 \times d^2 \text{ in.-lb}$$

where D = shaft diameter, inches; S_s = shear strength of pin material, pounds per square inch, and d = diameter of necked-down section of pin, in.

Shear-pin protection is supplied on request by most manufacturers of power transmission equipment, typically in the form of "breaking-pin hubs" on gears, sprockets, or flexible couplings. Two or more pins are provided, sharing the load to improve consistency: a maximum variation of 10% can be expected with six or more pins under nonfatigue conditions, as contrasted to the 50% variation typical of single pins. The multiple pins are placed parallel to the shaft in a ring around the flange and are fitted in hardened steel bushings to prevent flange mutilation.

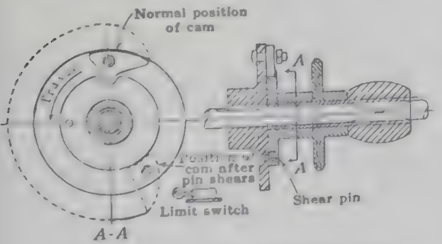


Fig. 19. Jeffrey telltale shear-pin hub.

A unique *telltale shear-pin hub* patented by *Jeffrey* is shown in Fig. 19. The limit switch stops the motor and gives warning through a bell or light if desired.

THE SAFETY WASHER, a variation of the shear pin, is sometimes applied for protection of worm gear drives. It consists of a cast-iron support cup which will break and permit the worm to screw itself away from a jaw coupling. A preloaded spring can also be used to support the worm.

A DETENT RELEASE COUPLING (noncommercial) is shown in Fig. 20. Relatively simple, this device has proved much more useful than the shear-pin coupling because it can be adjusted to within 5% of the load and resets itself without attention or time loss. A turnbuckle can be used to facilitate spring adjustment. If desired, the motor can be shut off automatically by driving the roller arm instead of the disk and placing a limit switch where it will be struck by the roller when out of the notch. Figure 21 illustrates another style suitable for light loads.

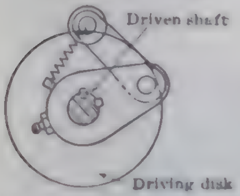

Fig. 20. Spring-loaded roller type detent release coupling. (Reproduced by permission from *Machine Design*)

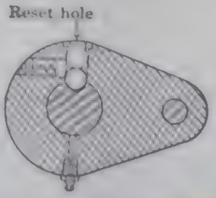

Fig. 21. Spring-loaded ball detent release coupling. (Reproduced by permission from *Machine Design*)

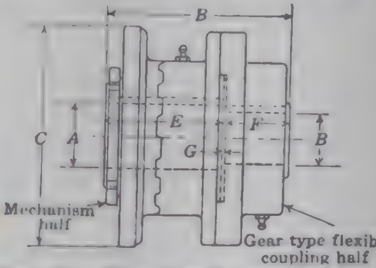

Fig. 22. Curvic tooth overload release coupling. See Table 16.

Figure 22 and Table 16 illustrate the Hilliard Curvic tooth overload release coupling. As a result of the snap action of the Belleville spring, this coupling releases completely and does not hammer. It is reset by force from the end, preferably by a built-in fork lever or by an air cylinder in the large sizes. In order to insure a return to the original relationship between shafts at reset, essential in timed mechanisms, one tooth can be removed and the opposite space filled in. This and other commercial overload release couplings can be obtained with sleeves for pulleys, gears, or sprockets as well as in the shaft cut-off design shown.

Table 16. Proportions and Capacities of Curvic Tooth Overload Release Couplings
(The Hilliard Corp., Elmira, N. Y.)

Note: Intermediate sizes also available.

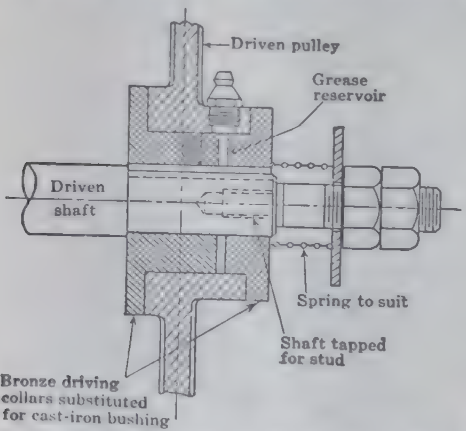

Fig. 23. Single-spring slip clutch applied to light V-belt pulley.

SLIP COUPLINGS are effective protection, particularly on a shock or pulsating load, because they can be set to the normal peak running load, yet will slip momentarily on abnormal peaks or fast starts—a cushioning action—without releasing completely. Slip couplings are also used to simplify construction and assure full travel in traverse drives and to provide controlled slippage in windup equipment.

Where the continued application of torque after slipping is objectionable or hazardous, a spring flapper can be built into the clutch to sound a warning, or a standard plugging switch can be belted to the output shaft to shut off the motor. Figure 23 illustrates a method for building slip action into existing light V-belt drives; Fig. 24 and Table 17 give dimensions of a standard coupling.

Overload slip action of varying sensitivity can be produced in most clutch types which do not operate on positive wedge or toggle locking principles, particularly in centrifugal, pneumatic, hydraulic, and magnetic clutches and couplings. (See discussion under Clutches.) Other power transmission elements with slip action include belts, particularly flat, round, and spring types, and certain friction variable-speed transmissions.

* Controlled torque hub may be mounted on either driving or driven shaft. Ordinarily it is mounted on smaller shaft.

† Same as standard flexible coupling hub. See Table 11 for complete coupling dimensions in these bore sizes.

CLUTCHES

By R. M. Nardone

Clutches are used to connect shafts to a driving mechanism such as a motor, engine, or line shaft, and to disconnect them at will. They may be classed as (1) friction clutches in which the driving force is transmitted by the friction of surfaces in contact, (2) jaw clutches in which jaws, dogs, or teeth in the two elements interlock, (3) hydraulic clutches (fluid couplings) in which torque is transmitted hydrodynamically through change of momentum of a moving fluid, and (4) electromagnetic clutches in which torque is transmitted across an air gap through the creation of an electromagnetic field. In addition, there are overrunning or freewheeling clutches which permit torque transmission in one direction only.

9. FRICTION CLUTCHES

MULTIPLE-DISK CLUTCHES are usually of the multiple-plate type in which one set of disks is splined to one shaft and the other set, alternating with the first, is splined to the other shaft (Fig. 1). Pressure on the clutch pack is usually applied by one or more springs which are either adjusted to impose a steady pressure on the disks or which may be regulated for varying pressure. Let P = total spring force, pounds; r = mean radius of disks, inches; n = number of slipping surfaces; μ = coefficient of friction; and T = torque capacity of clutch, lb-in. Then

$$T = P \cdot \mu \cdot n \cdot r \tag{1}$$

Slipping surfaces are usually steel against bronze but may be asbestos against steel, cork on steel, etc. The coefficient of friction of bronze on steel with grease lubrication, is approx. 0.15. Without lubrication, μ varies between 0.2 and 0.25. For an asbestos surface, the friction coefficient is usually 0.3 to 0.4.

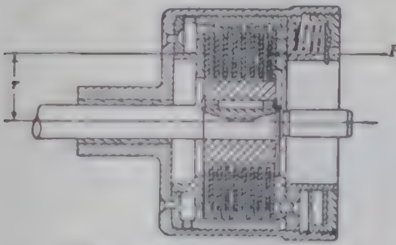

Fig. 1. Multiple-disk clutch.

Heating of the clutch depends on the amount of slipping or the energy absorbed during operation. The temperature rise is

$$(t_1 - t_2) = \frac{H}{WC} = \frac{E}{778.3WC} \tag{2}$$

where t_1 = maximum temperature of the clutch disks, degrees F; t_2 = initial disk temperature; H = heat absorbed by clutch, (Btu); E = energy, foot-pounds; W = weight of clutch plates, pounds; and C = specific heat of clutch plate material.

The amount of energy absorbed by the clutch is equal to

$$E = \frac{T \times 2\pi}{12} \times N = \frac{TN\pi}{6} \tag{3}$$

where N = number of revolutions of slip. A temperature t_1 of 500 F should not be exceeded.

Capacity. All types of friction clutches should have torque capacities of double the torque delivered to them in order to start the load from rest without excessive slip. That is, the torque to be transmitted should be multiplied by a static load factor of 2. If the torque delivered to the clutch is irregular, as in certain types of internal combustion engines, the static load factor should be increased from 2 to possibly 3 or 4.

Additional factors should be applied depending on the character of the load. Table 1 gives factors recommended by the Twin Disc Clutch Co. as a guide in the selection of a clutch based on the characteristics of the driven mechanism.

Table 1. Application Factors for Dry-plate Friction Clutches

Driven Mechanism	Factor	Driven Mechanism	Factor
Air compressors (depending on cycles)	2.00–2.50	Generator, steady load	1.00
Ammonia compressors	2.50	Hammer mills	2.00
Blowers	1.00	Hoists, elevators, cranes, shovels	2.00
Brick-making and similar machinery	3.00	Line shaft (driven by belt or gears)	1.50
Centrifugal pumps	1.00	Printing presses, textile looms, etc.	1.50
Crushers, veneers, hogs, ball mills, etc.	2.00	Pulp grinders, screens, etc.	1.75

CENTRIFUGAL CLUTCHES. A centrifugal clutch produces its torque by virtue of the centrifugal force of weights pressing against the driving or frictionally driven member. The simplest form is shown in Fig. 2 where two weights A are shown connected to and driven by motor B and separated from each other by springs C so as to press against the inside diameter of the driving drum E.

Referring to Fig. 2, let R = inside radius of drum E, inches; r = radius of gyration of weights A, inches; w = weight of the centrifugal member A, pounds; μ = coefficient of friction; F_c = total centrifugal force of weights A, pounds; P = spring force on each weight,

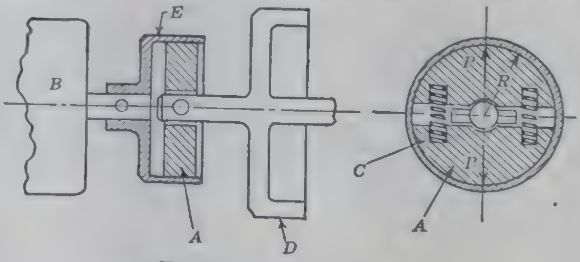

Fig. 2. Centrifugal clutch.

pounds; T_1 = torque due to spring force, pound-feet; T_2 = torque due to centrifugal action of weights A, pound-feet; T = total torque at any speed, pound-feet; t = time required to accelerate flywheel D, seconds; ω = speed of flywheel, radians per second; n = number of centrifugal weights; I = total moment of inertia of driven members, pound-feet second squared; and α = acceleration, radians per second per second. Then

$$T_1 = \frac{P\mu Rn}{12} \tag{4}$$

$$F_c = \frac{wr\omega^2 n}{12g} \tag{5}$$

$$T_2 = F_c \times \frac{\mu R}{12} = \frac{wr\omega^2 Rn\mu}{g \times 12 \times 12} \tag{6}$$

$$T = T_1 + T_2 = \frac{P\mu Rn}{12} + \frac{Wr\omega^2 \mu Rn}{144g} \tag{7}$$

But $T = I\alpha$ = torque resistance of flywheel D. Therefore

$$I\alpha = \frac{P\mu Rn}{12} + \frac{wr\omega^2\mu Rn}{144g}$$

and

$$\alpha = \frac{P\mu Rn}{12I} + \frac{wr\omega^2\mu Rn}{144gI} \tag{8}$$

Let

$$C = \frac{P\mu Rn}{12I} \quad \text{and} \quad K = \frac{wr\mu Rn}{144gI}$$

Then

$$\alpha = C + K\omega^2 = \frac{d\omega}{dt}$$

$$dt = \frac{d\omega}{C + K\omega^2}$$

$$t = \int \frac{d\omega}{C + K\omega^2} = \frac{1}{\sqrt{KC}} \times \tan^{-1} \omega \sqrt{\frac{K}{C}} \text{ seconds} \tag{9}$$

Example: Required: to accelerate flywheel D to 6000 rpm. How long will it take? Motor speed and torque are at all times greater than flywheel speed and transmitted torque, respectively. Proportions are as follows: I = 0.007 lb-ft sec^2; $n = 2$; P = 1 lb; $\mu = 0.2$; R = 2 in; w = 1 lb, each; and r = 1.5 in. Then

$$C = \frac{P\mu Rn}{12I} = \frac{1 \times 0.2 \times 2 \times 2}{12 \times 0.007} = 9.52; \qquad K = 0.037; \qquad \sqrt{KC} = 0.593$$

$$\frac{1}{\sqrt{KC}} = 1.685; \qquad \sqrt{\frac{K}{C}} = 0.0624$$

$$t = 1.685 \tan^{-1} \omega \times 0.0624$$

$$\omega = 630 \text{ radians per sec (approximately)}$$

$$t = 1.685 \tan^{-1} 630 \times 0.0624$$

$$= 1.685 \tan^{-1} 39.3$$

$$\tan^{-1} 39.3 = 88.54 \text{ degrees} = 1.55 \text{ radians}$$

Therefore

$$t = 1.685 \times 1.55 = 2.61 \text{ sec}$$

CONE CLUTCHES. **The conical friction clutch** consists of the frustum of a cone, so fitted to a shaft by means of a feather key that it can be pushed into an opposite engaging surface rigidly attached to the other shaft. Such clutches require some force to put them into gear. This force, acting parallel to the shaft, produces an undesirable end thrust. Cone clutches may be faced with leather or asbestos fabric or equipped with cork inserts to increase their driving capacity. The inclination α of the slant side is highly important in order to avoid "sticking" on the one hand, and too sudden seizure on the other. α usually ranges from 7 1/2 to 13 degrees. Proportions may be taken as follows (see Fig. 3): $B = 2d + 1$; $C = 1.5d$; $F = 1.8d$; $H = 0.5d$; $E = 0.4d + 0.4$; $G = 0.3d + 0.3$; $t = 0.2d + 0.1$; $L = 2d$.

Formulas for Cone Clutches (Fig. 3). Let M = moment clutch is capable of transmitting, inch-pounds; hp = horsepower transmitted; N = revolutions per minute; r_2 = small radius of friction cone, inches; r_1 = large radius of friction cone, inches; r = mean radius of friction cone, inches; V = velocity of a point at distance r from center, feet per minute; T = total tangential force acting at radius r, pounds; P_n = total normal pressure between cone surfaces, pounds; p = allowable pressure, pounds per square inch of contact surface; P_s = total axial or spring pressure, pounds, α = angle of clutch surface with axis of shaft; w = width of cone surface, inches; and μ = coefficient of friction. Then

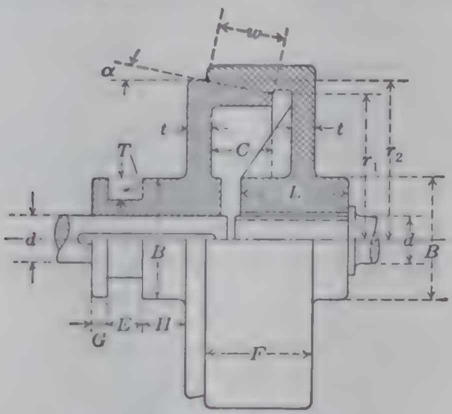

FIG. 3. Conical friction clutch.

$$r = {}^1/_2(r_1 + r_2); \qquad M = Tr; \qquad T = \mu P_n; \qquad V = {}^1/_{12}(2\pi rN); \qquad w = \frac{P_n}{2\pi rp}$$

For engagement without slip,

$$\text{Hp} = \frac{P_n \mu rN}{63{,}030}$$

$$P_s = \frac{T}{\mu}(\sin\alpha + \mu\cos\alpha) = \text{hp} \times 63{,}030\left(\frac{\sin\alpha + \mu\cos\alpha}{\mu rN}\right)$$

and after engagement

$$P_n = \frac{P_s}{\sin\alpha}$$

$$P_s = \text{hp} \times \frac{63{,}030}{\mu rN}\sin\alpha$$

The allowable normal pressure p may be taken as 7 or 8 psi for leather bands, according to *Machinery's Handbook;* Smith and Marx give values of 30 to 40 psi for leather or cork, and 35 to 45 psi for maple wood. For values of friction coefficient, see Table 4, p. 7-28.

MAGNETIC CLUTCHES are a form of friction clutch in which the friction surfaces are brought into contact by an electromagnet instead of by mechanical means. They may be operated at higher rotative speeds than mechanical clutches and are recommended for heavy duty where mechanical clutches are impractical, for high-speed drives, and where the motor cannot start a heavy load. The principle of the clutch is shown in Fig. 4. A magnet coil A, carried by one member of the clutch, attracts to itself the armature B, carried by a spring plate C, which flexes when the magnet is energized. A friction ring D, carried by the armature, is faced with friction lining F. When the coil A is energized, the friction lining is drawn into contact with field friction ring E. The friction between E and F transmits the torque from one clutch member to the other. For heavy duty, two friction linings often are used. See Fig. 5.

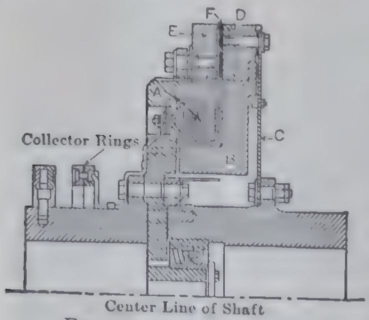

FIG. 4. Magnetic clutch.

The clutch is engaged by energizing the magnet coil; it is disengaged by de-energizing the coil. The spring plate then pulls the friction lining away from the friction ring until there is an idling clearance of about $^1/_{16}$ in. between them. The current in the magnet coil is varied by a manually operated controller, which permits the torque to be built up gradually. Heavy loads thus can be started without shock.

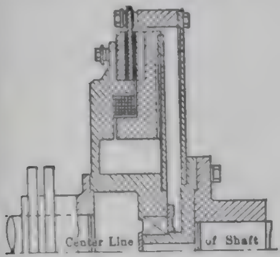

FIG. 5. Heavy duty magnetic clutch.

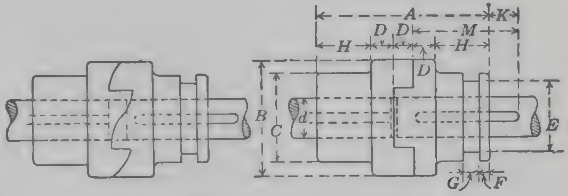

FIG. 6. Jaw clutches.

10. POSITIVE-ENGAGEMENT CLUTCHES

JAW CLUTCHES (Fig. 6) are used for slow-moving shafts, where sudden starting action is not objectionable and when the inertia of the driven parts is relatively small. The various forms of such clutches differ only in the shapes or angles of the engaging surfaces. One-half of the coupling is fitted with a feather key, permitting it to be engaged with or disengaged from the other half at will.

If N = number of teeth, R = mean radius of clutch tooth, A = area of engaging face of one tooth, A' = area of the tooth subjected to shear, s_c = allowable unit crushing stress of the clutch jaw, and s_s = allowable shearing stress of the shaft, then the relation between strength of the shaft and strength of clutch is

$$^1/_{16}\, s_s \pi d^3 = RNAs_c = RNA's_s \tag{10}$$

The spiral form (Fig. 6) is more easily put into gear, but the motion of the shaft always must be in the same direction. Table 2 gives the proportions used by one maker for both square and spiral jaw clutches.

Table 2. Dimensions of Square and Spiral Jaw Clutches

(Data from Dodge Mfg. Co., Mishawaka, Ind.)

Synchronized Engagement. Another form of jaw or dog clutch is used in automotive transmissions. The clutch elements comprise an external and internal gear or spline, each element having the same number of teeth. One member slides on a spline connection into and out of mesh with the other, at the will of the operator. Clashing due to speed differences is prevented by synchronizing clutches, usually consisting of small friction clutches which engage through a detent mechanism prior to the tooth engagement. To make the speed synchronization possible, one of the elements must be free to accelerate or decelerate to the speed of the other during engagement. In automobiles this is done by releasing the main friction clutch.

11. HYDRAULIC COUPLINGS OR FLUID CLUTCHES

In a fluid clutch, an impeller and a runner are enclosed in a housing filled with a light oil. The two members are the shape of two hollow doughnuts, one within the other and split in half along the circular axis. The impeller is connected to the driving shaft and the runner to the driven shaft. (See Fig. 7.) The liquid is set in motion by the radial blades of the impeller and is dashed against similar blades in the runner. A drag is thereby produced on the runner, causing it to rotate with the impeller.

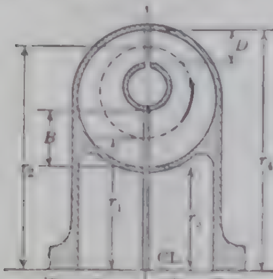

Fig. 7. Fluid clutch.

The liquid carried by the coupling around the shaft axis has centrifugal force imparted to it. This force pushes the liquid out of the impeller into the slower rotating runner, and the difference in centrifugal force causes rapid circulation of the fluid in the torus parallel to the radial vanes.

Power is transmitted almost wholly through the loss of kinetic energy caused by the difference in the linear tangential velocity of the liquid at the outlet D of the impeller and the lower tangential velocity at outlet B of the runner. The impeller horsepower is usually greater than that of the runner due to the differences in their speeds. However, the torque on both members is always equal, that is, impeller torque equals runner torque.

If the physical dimensions of the coupling, and the impeller and runner speeds are known, the loss in kinetic energy, transmitted horsepower, and torque may be calculated. Most couplings are designed to have the cross-sectional area of the liquid path constant. Therefore, radial width B equals $D \times r_2/r_1$. Design formulas are given in Table 3.

Table 3. Fluid Clutch Design Formulas

(See Fig. 7 and nomenclature below)

$$B = \frac{r_2}{r_1} D \tag{11}$$

$$Q = \frac{a \cdot 2\pi(r_2 + r_1)}{2} \times 0.85 \quad \text{(0.85 is factor to compensate for volume of radial blades)} \tag{12}$$

$$W = Qd \tag{13}$$

$$F_i = \frac{W}{4g} \cdot \frac{(r_2 + r_1)}{2 \times 12} \cdot \left(\frac{2\pi N}{60}\right)^2 = \frac{W(r_2 + r_1)N^2}{282{,}000} \tag{14}$$

$$F_r = \frac{W}{4g} \cdot \frac{(r_2 + r_1)}{2 \times 12} \cdot \left(\frac{2\pi n}{60}\right)^2 = \frac{W(r_2 + r_1)n^2}{282{,}000} \tag{15}$$

$$F = F_i - F_r \tag{16}$$

$$L = \frac{\pi(r_2 - r_1)}{12} \tag{17}$$

$$H = \frac{F}{A \cdot d \cdot 12} \tag{18a}$$

$$H = f\left(\frac{12L}{D}\right)\frac{V^2}{2g} \tag{18b}$$

$$A = 2\pi r_2 \cdot D \tag{19}$$

$$P = 12VZAd \tag{20}$$

$$KE_i = \frac{Pv_i^2}{2g} \tag{21}$$

$$KE_r = \frac{Pv_r^2}{2g} \tag{22}$$

$$KE = KE_i - KE_r \tag{23}$$

$$v_i = \frac{2\pi r_2}{12} \times \frac{N}{60} \tag{24}$$

$$v_r = \frac{2\pi r_1}{12} \times \frac{n}{60} \tag{25}$$

$$\mathrm{HP}_i = \frac{KE}{550} \tag{26}$$

$$T = \frac{\mathrm{HP} \times 5250}{N} \tag{27}$$

In Table 3,

N = impeller speed, revolutions per minute.
n = runner speed, revolutions per minute.
F_i = centrifugal force on liquid in impeller, pounds.
F_r = centrifugal force on liquid in runner, pounds.
F = net centrifugal force causing vortex circulation, pounds.
d = density of liquid = .032 lb per cu in. for usual oils of 0.875 specific gravity.
s = specific gravity of liquid = 0.875, average.
μ = absolute viscosity of liquid, poises.
L = circuit length, feet; dotted line in Fig. 7.
H = hydraulic head, feet.

V = velocity of liquid along path L, feet per second.
v_i = linear velocity tangential to shaft rotation of liquid at outlet of impeller, feet per second.
v_r = linear velocity tangential to shaft rotation of liquid at outlet of runner or inlet to impeller, feet per second.
W = total weight of liquid circulating, pounds.
A = mean average area, transverse to vortex circuit at outlet of impeller, square inches.
f = friction factor in formula $H = f\left(\frac{12L}{D}\right)\frac{V^2}{2g}$ (see Fig. 8).
D = radial width of vortex path at impeller outlet, inches.
B = radial width of vortex path at impeller inlet, inches.
K = criterion used to find $f = DVs/100\mu$ (see Fig. 8).
Z = turbulence friction factor = 0.80 for high slip to 0.95 for viscous flow.
a = area of liquid circulating around circuit L, square inches.
Q = total volume of liquid circulating, cubic inches.
r_2 = equivalent mean radius of outflow from impeller, inches.
r_1 = equivalent mean radius of inflow to impeller, inches.
g = acceleration of gravity = 32.2 ft per sec^2.
P = fluid circulating rate, pounds per second.
KE_i = kinetic energy delivered by impeller, foot-pounds per second.
KE_r = kinetic energy received by impeller, foot-pounds per second.
$KE = KE_i - KE_r$ = difference in kinetic energy, foot-pounds per second.
HP_i = horsepower delivered by impeller.
HP_r = horsepower delivered by runner to output shaft.
T = torque, pound-feet.

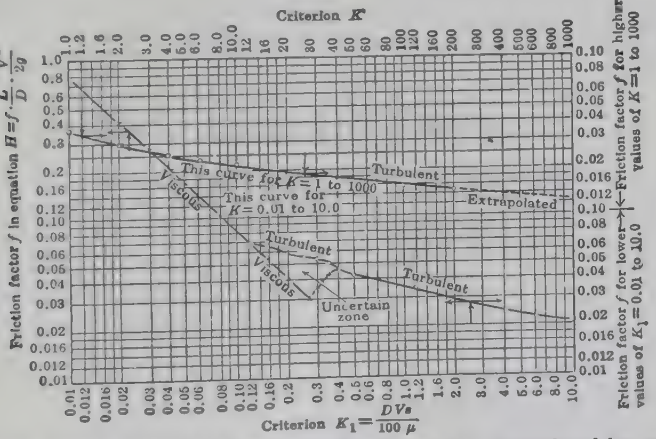

FIG. 8. Chart for friction factor f as a function of criterion K. (Reproduced by permission from *Product Engineering*, Dec. 1942)

EXAMPLE. Find the horsepower that can be transmitted by the coupling shown in Fig. 7 at 2000-rpm impeller speed and 5% slip, given the following dimensions: Let r_3 = 3.0 in., r_4 = 7 in., D = 1 in., $r_2 = r_4 - (D/2) = 7 - 0.5 = 6.5$ in. Since N = 2000 rpm, n = 1900 rpm.

Area at D must equal area at B; therefore, $2\pi r_2 D = 2\pi[r_3 + (B/2)]B$. Substituting for r_2, r_3, and D, and solving for B, B = 1.7 in.; hence $r_1 = 3 + 0.85 = 3.85$ in. Therefore, diameter of inner ring $= r_4 - r_3 - B - D = 1.3$ in.

Cross-sectional area of circulating liquid $= a = (\pi/4)(4^2 - \overline{1.3}^2) = 11.25$ sq in. From eq. 12, volume Q = 311 cu in, and, from eq. 13, $W = 311 \times 0.032 = 10$ lb, approximately.

The centrifugal force on $W/2$ lb of the liquid in the impeller is, from eq. 14,

$$F_i = \frac{10 \times (6.5 + 3.85) \times 2000^2}{282{,}000} = 1470 \text{ lb}$$

and the centrifugal force on the liquid in the runner is, from eq. 15,

$$F_r = \frac{10 \times (6.5 + 3.85) \times 1900^2}{282{,}000} = 1330 \text{ lb}$$

The difference in centrifugal force is, from eq. 16, $F = 1470 - 1330 = 140$ lb. The mean average area $A = 2\pi \times 6.5 \times 1 = 40.9$ sq in. from eq. 19; therefore, the hydraulic head $H = 140/(40.9 \times 0.032 \times 12) = 8.9$ ft, from eq. 18a.

For trial purposes, assume a reasonable value for the velocity of liquid circulation in the vortex, V. Using $V = 30$, $s = 0.875$ specific gravity, and $\mu = 1$ absolute viscosity, criterion K (Fig. 8) is $K = (DVs)/100\mu = (1 \times 30 \times 0.875)/(100 \times 1) = 0.2625$.

From Fig. 8, $f = 0.056$. Using eq. 18b, calculate V. If the value so found comes within 5% of the assumed value, use it in succeeding calculations. Otherwise, recalculate.

From eq. 17, $L = \pi(6.5 - 3.85)/12 = 0.695$ ft.

Substituting in eq. 18b, $8.9 = 0.056 \times 12 \times 0.695 \times V^2/64.4$, from which $V^2 = 1210$ and $V = 35$. With $V = 35$, $K = 0.36$, $f = 0.054$, and $V = 35.5$ ft per sec.

Pounds of fluid circulating, taking turbulence friction factor $Z = 0.85$, is, from eq. 20, $P = 12 \times 35.5 \times 0.85 \times 40.9 \times 0.032 = 475$ lb per sec.

The kinetic energy of the liquid in the impeller is calculated from eq. 21, where v_i, from eq. 24, is $(2\pi \times 6.5 \times 2000)/(12 \times 60) = 113.7$ ft per sec. Equation 21 therefore gives $KE_i = (475 \times 113.7^2)/64.4 = 95{,}500$ ft-lb per sec. In like manner, eq. 25 gives $v_r = (2\pi \times 3.85/12) \times (1900/60) = 63.9$ ft per sec, and eq. 22 gives $KE_r = (475 \times 63.9^2)/64.4 = 30{,}100$ ft-lb per sec.

Difference in $KE = 95{,}500 - 30{,}100 = 65{,}400$ ft-lb per sec. Therefore, impeller horsepower $Hp_i = 65{,}400/550 = 118.5$, transmitted torque $T = (118.5 \times 5250)/2000 = 310$ lb-ft; and output shaft horsepower $Hp_r = (310 \times 1900)/5250 = 112.5$ hp.

Applications. Hydraulic couplings are commercially available (see Article 29 in this section) and are used for a variety of purposes as clutches (by emptying and filling as required), as variable-speed drives (by partial emptying), and to minimize shock and vibration.

ELECTROMAGNETIC CLUTCHES. If the basic elements (field and armature) of an electric motor are so mounted that one is attached to a driving shaft and the other to the driven, the result is a unit which may function as a clutch. When energized by an external source of d-c excitation the clutch transmits torque, but when de-energized it disconnects the driving and driven shafts by removing the electromagnetic field across the air gap.

Speed-torque characteristics of such a clutch are somewhat similar to those of a fluid coupling. They are used in similar applications as clutches, as variable-speed drives, and as shock-absorbing couplings. When they are operated at less than full output speed, power is dissipated. The coupling must be well ventilated under such conditions.

12. OVERRUNNING CLUTCHES

Freewheeling clutches are employed when one shaft is intended to drive another but the second shaft cannot drive the first in the same direction of rotation.

ROLLER CLUTCH. Figure 9 shows a roller assembly of one type of roller clutch in which A is the driving member, B the driven number, and C one of a number of similar rollers equally spaced about the cam member. The roller contacts the inner diameter of A and a flat or cam surface on B. A spring is normally used to keep the roller in light contact with both driving and driven members.

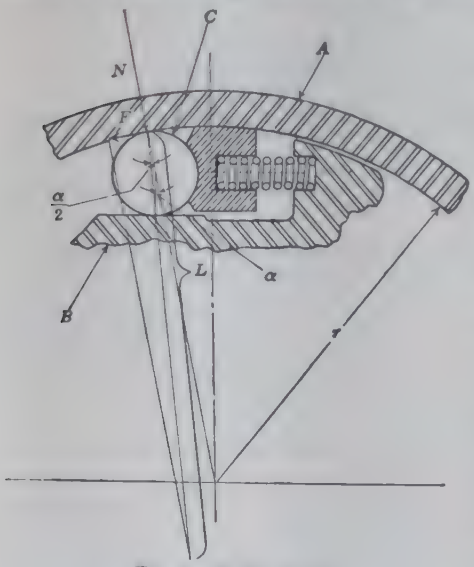

Fig. 9. Roller clutch.

Referring to Fig. 9, let T = total driving torque, pound-inches; F = driving force due to T, pounds; N = normal force on roller, pounds; r = internal radius of A, inches; α = angle formed by a radius passing through the center of the roller and a perpendicular from roller center to its point of contact with B, degrees; L = resultant of F and N, pounds; l = length of roller, inches; and n = number of rollers. Then $L = F/[\sin(\alpha/2)]$ pounds; $F = T/nr$ pounds from which $L = T/[nr \sin(\alpha/2)]$ pounds (force at contact points of roller).

Then L/l, which is the pounds per inch of roller length, should not exceed 25,000 under worst condition of operation.

The half angle $\alpha/2$ should be between 2 and 6 degrees.

SPRING CLUTCHES. A number of different types and forms of spring clutches are in use. The external type shown in Fig. 10 is in effect a band brake connecting two cylinders placed end to end and rotating on a common axis. The spring is assumed fastened to the left-hand arbor and slips on the right-hand arbor when that arbor is rotated clockwise. The spring is initially wound somewhat smaller as to its inner diameter than the outside diameter of the arbor. The inner radial force per unit length of the spring on the arbor is assumed to be constant when no torque is applied. This force f_0 depends on the amount the spring has to be opened up in order to slide it over the arbor.

Referring to Figs. 10 and 11, let f_0 = radial force of spring on arbor when no torque is applied, pounds per inch of contact line; r_2 = radius of arbor, inches; T = torque transmitted, inch-pounds; e = base of Napierian system of logarithms = 2.71828; N = number of turns on right-hand arbor or driving drum; μ = coefficient of friction (approximately 0.15); R_2 = radius to neutral axis of wire when spring is on arbor, inches; R_1 = radius to neutral axis, spring free, inches; E = Young's modulus for the spring material, pounds per square inch; and I = the area moment of the wire section, inches⁴. Then $f_0 = EI[(R_2 - R_1)/R_1R_2^2r_2)]$ pounds per inch, and $T = r_2^2f_0(e^{2\pi N\mu} - 1)$ inch-pounds. The torque increases rapidly with an increase in N. Limiting torque is the product of r_2 and the breaking strength of the spring wire.

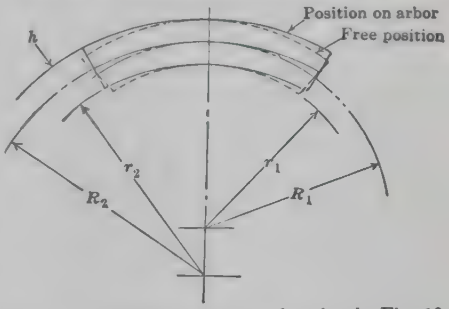

Fig. 11. Enlarged segment of spring in Fig. 10.

PULLEYS

By W. A. Williams

13. CAST-IRON PULLEYS

Cast-iron pulleys, as contrasted with wood or steel pulleys, are particularly adapted for service in plants where excessive dampness or acid fumes may be prevalent, such as in chemical plants, tanneries, dye houses, paper mills, textile plants, etc. Because of their relatively greater weight, they lend themselves to installation wherever kinetic energy or flywheel effect is desired in the transmission system.

Pulleys for the transmission of power or for use on conveyors have been standardized by manufacturers, and stock pulleys are available for practically all installations. The design of pulleys, except for special conditions, is not necessary. It usually will prove more economical to consult manufacturers of pulleys for the possible adaptation of a stock pulley to meet the special condition.

SIZES AVAILABLE. Cast-iron pulleys are manufactured in sizes ranging from 3-in. diameter by 2-in. face to 72-in. diameter by 40-in. face for transmission purposes. For conveyor applications, widths up to 75 in. are available.

TYPES OF PULLEYS. A wide variety of types are manufactured to meet practically every conceivable condition. Cast-iron pulleys are made with solid rim and hub, solid rim and split hub, and two types of split rim and split hub. Specific design depends on the manufacturer and size of the pulley. For light-duty service, six-arm split pulleys are made by fracturing the rim so that when installed and tightened on the shaft they have a smooth, uninterrupted face, run true, and can be balanced as accurately as solid pulleys.

Crown taper ⅛ in. to the foot exaggerated here for illustration

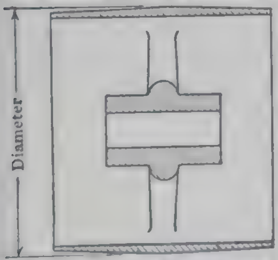

Fig. 1. Standard crown and diameter measurement of pulleys.

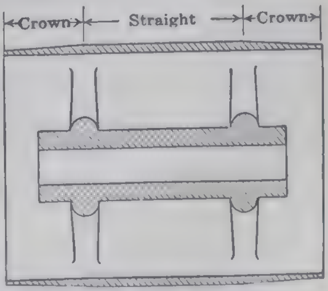

Fig. 2. Wide-face double-arm pulley with flat center portion.

Pulleys can be furnished with either flat, crown, or flanged rims. Pulleys are crowned to keep the belt on the pulley. There has been a tendency to reduce the crown on pulleys, since severe crown is detrimental to belts, and no amount of crown will correct poor alignment. The amount of crown used on most transmission pulleys does not exceed $^1/_8$ in. to the foot. Wide-face pulleys usually require less taper, or the center half of the pulley is left flat. Figure 1 shows the crown on single-arm pulleys, and Fig. 2 shows the flat crown often used on double-arm wide-face pulleys.

FLANGES may be added to the outside of the pulley at extremities of the rim to retain the belt, or a single flange may be added to the center of the pulley to separate two belts. Flanges may be placed on the inside of the rim to stiffen the rim and to permit bolting two pulleys together.

HUBS are usually made in one of three styles. Straight solid hubs are provided with a keyway and two setscrews, one over the key and one 90 degrees away from it. Split hubs are either split on one side only and provided with two bolts to tighten the pulley to the shaft, or are split on both sides and provided with four bolts. They may or may not be equipped with keyways, depending on the magnitude of the load. On light loads the compression or clamping action provided by the bolts is sufficient to keep the pulley tight on the shaft. Pulleys may also be equipped with one of various designs of tapered bushings which permit the use of pulleys on any shaft size within the limits of the pulley bore. These bushings permit the omission of a key except on applications where severe loads or shock loads are encountered.

PROPORTIONS OF CAST-IRON PULLEYS. The specific proportions of cast-iron pulleys vary somewhat among various manufacturers, depending on the type of industry the pulleys were originally designed for and on the particular foundry and manufacturing methods in use. Commercial stock pulleys are made with three or four arms up to 10 in. in diameter, six arms from 11 to 74 in. in diameter, and eight arms for larger diameters. Pulleys with two or three sets of arms may be considered as two or three separate pulleys combined in one. Releaux states in such cases that the proportions of the arms should be 0.8 or 0.7 those of single-arm pulleys.

The arms on most cast-iron pulleys, flywheels, and sheaves are elliptical in section. This shape combines neatness in appearance, low windage loss, and high strength in the direction of rotation. It is also a section that is easily molded and cast. For minimum weight with equivalent strength, an H section is preferable, but some sacrifice in appearance and increase in windage must be expected.

ALLOWABLE RIM SPEED. The following rim speeds are the maximum speeds advisable for cast-iron pulleys:

Regular iron pulleys	Solid or split	3750 ft per min
Regular iron pulleys	Specially balanced solid or split	4500 ft per min
Split-arm iron pulleys	Six-arm pulleys through two opposing arms, rather than between arms specially balanced	6000 ft per min
Specially designed solid iron pulleys	Specially balanced	7000 ft per min

Should rim speeds above 7000 ft per min be necessary, the manufacturer should be consulted and material other than cast iron should be selected for the pulley construction.

CAPACITY OF STANDARD PULLEYS. As regularly listed, cast-iron pulleys are designed and built to withstand the stresses which may be placed upon them by medium double leather belts, or their equivalent, as figured on a basis of 65 lb of effective tension per inch of width. Pulleys may also be obtained for heavy double-belt service based on an effective tension of 90 lb per inch of width, or for triple-belt service based on an effective tension of 120 lb per inch of width. For extreme service conditions, pulleys can be furnished for effective tensions up to 210 lb per inch of width.

14. STEEL PULLEYS

STEEL SPLIT PULLEYS. The vast majority of pulleys used in flat-belt power transmission are steel split pulleys. The reasons for this are their low cost, light weight, greater availability, and the fact that they are made with interchangeable bushings which permits their use on any shaft up to the maximum bore of the pulley.

Steel split pulleys are manufactured in standard sizes from 3-in. diameter by 2-in. face up to 144-in. diam. by 36-in. face. Standard pulleys are manufactured in diameters 1 in. apart up to 16 in. and 2 in. apart up to 72 in. Pulleys above 72 in. are made on order only.

TYPES OF CONSTRUCTION. Details of construction by different manufacturers vary with diameter, face width, and duty. In general, a two-arm construction is used on small pulleys, six-arm on intermediate sizes up to 44 in., and eight-arm on pulleys over 44 in.

Heavy-duty pulleys are made with the disk center construction, or with heavier arms with additional support gussets between the arms and the rims, and with heavier hub construction.

Pulleys can be obtained with single, double, or triple flanges.

ALLOWABLE RIM SPEEDS. Recommended rim speeds vary between 5000 and 6000 ft per min, depending on pulley sizes, construction, and manufacturer. In general, the manufacturer should be consulted when rim speeds of over 5000 ft per min are contemplated.

SOLID-STEEL CONVEYOR PULLEYS. A relatively new type of steel pulley now being manufactured is the solid-steel conveyor pulley illustrated by Fig. 3. These pulleys, with interchangeable cast-iron hubs, are manufactured in the following standard diameters: 6, 8, 10, 12, 14, 16, 18, 20, 24, 30, 36, 42, 48, 54, and 60 in. Standard face widths are: 12, 14, 16, 18, 20, 22, 24, 26, 30, 32, 36, 38, 42, 44, 48, 51, 63, 70, and 76. On these pulleys, the actual face should exceed the belt width by 2 in. for belts up to 42 in.; by 3 in. for belts of 48, 54, and 60 in.; and by 4 in. for belts of 66 and 72 in.

The crown on these pulleys is held to $^1/_{16}$ to $^1/_8$ in. of increment of pulley diameter per foot of total pulley width on pulleys up to 26-in. face width, inclusive; $^3/_{64}$ to $^5/_{64}$ in. of increment of pulley diameter per foot of total pulley width on pulleys over 26-in. face width.

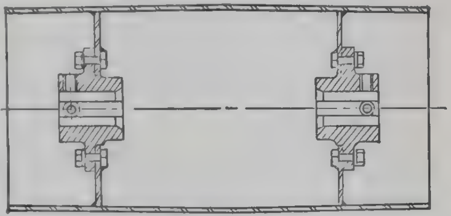

FIG. 3. Steel conveyor pulley.

The above standards were adopted by the Power Transmission Association as applicable to all manufacturers making steel conveyor pulleys who are members of that Association. These pulleys have found wide acceptance on all classes of conveyor application and can also be used for power transmission service where heavy-duty conditions, at relatively slow speeds, are encountered.

IRON SPIDER STEEL RIM PULLEYS. A design that eliminates the shrinkage strains inherent in cast-iron pulleys is made with cast-iron spider to which a rolled steel rim is riveted. These pulleys are made for heavy-duty service and can be made for exceptionally high-speed service.

15. NONMETALLIC PULLEYS

WOOD PULLEYS. Pulleys made entirely of wood are available for service where lightness is important and where moisture and fire hazard are not prevalent. Claims are made that wood pulleys provide a higher coefficient of friction against a leather belt than cast-iron or steel, but available test data do not seem conclusive.

In addition to all-wood pulleys, wood-rim pulleys with cast-iron spiders are also available.

A special form of wood pulley used mostly for motor pulleys is made of laminated layers of soft wood cemented together and compressed under heavy pressure until the thickness has been substantially reduced, thereby increasing the density of the wood. The laminated layers make it possible to insure that end-grain wood is uniformly distributed over the face of the pulley, to provide uniform wear resistance. These pulleys have ribbed cast-iron hubs which are forced into undersized holes in blocks of the laminated wood. They are available in either bushed or on-bore construction, in sizes from 1 $^1/_2$ by 1 $^1/_2$ in. up to 24 by 24 in. Faces may be either crown, straight, stepped, or flanged in any combination. With standard pulleys, belt speeds up to 6000 ft per min are common, and with specially balanced pulleys, 10,000 ft per min.

PAPER PULLEYS. Paper pulleys made of impregnated paper board are used particularly for motor pulleys. They are also popular in any service requiring high coefficient of friction. In small sizes the hub is cast within the fiber; in medium sizes a tapered hub is pressed into the material; and in larger sizes rings of paper board are assembled onto a cast-iron spider. Other pulleys are made with a web center. Recommended rim speed is 5000 ft per min for standard paper pulleys, and 10,000 ft per min for specially balanced pulleys.

RELATIVE CAPACITY OF DIFFERENT TYPES OF PULLEYS. The capacity of a pulley depends on so many factors other than the actual make-up of the pulley itself that it is unwise to accept the results of any test as conclusive unless all variables have been considered. Factors which can influence performance are: type of belt (hard, soft), age of belt, type and amount of belt dressing used, crown of pulleys, age of pulleys (if impregnated type), belt speed, size of pulleys, and load per inch on belt in comparison with recommended rating. After consideration of all the above factors, it will still be necessary to arrive at an acceptable criterion of performance.

In an investigation to ascertain the value of compressed spruce pulleys, Professor G. S. Wilson (*Bulletin* 10, Univ. of Wash. Eng. Expt. Sta., 1920) found the horsepower capacity of several different types of pulleys to be as given in Table 1. In this investigation the slip of the belt was measured at belt tensions ranging from 37 $^1/_2$ to 187 $^1/_2$ psi of belt section, and the horsepower determined by a Prony brake. The pulleys used in the investigation were 18-in. diameter and 6-in. face.

Table 1. Horsepower Capacities per Inch Width of Belt of Various Pulleys

Type of Pulley	Weight, lb	Slip of Belt			Relative Capacity at 2% Slip
		1%	1 1/2%	2%	
		Horsepower			
Cast iron	65.0	.58	.69	.74	100.0
Steel	40.0	.71	.78	.81	109.4
Wood split	21.5	.63	.77	.82	110.8
Paper	41.5	.62	.76	.83	112.1
Compressed spruce	22.0	.76	.81	.84	113.5

A paper by Lawrence Whitcomb (National Association of Cotton Manufacturers, 1909) gives the results of tests made at the Lowell Textile School on the relative transmitting capacity of wood-rim, wood-rim with cork inserts, wood-rim lagged with leather, and steel pulleys, all 18 in. diameter by 6-in. face. The results of the tests are summarized in Table 2.

Table 2. Tests of Lagged and Cork Insert Pulleys

Type of Pulley	Horsepower at 2% Slip	Maximum Horsepower Transmitted	Slip, % at Maximum Horsepower	Relative Value at 2% Slip
Wood rim, cork inserts	11.8	13.2	4.6	100%
Wood rim, leather-lagged	8.7	12.4	4.7	73%
Steel	8.3	12.7	6.0	70%
Wood rim	7.8	9.6	4.3	65%

Recent tests conducted by Professor M. L. Price of Worcester Polytechnic Institute on various pulleys and belts under identical horsepower conditions show the wide variation that can be expected in results. Tests were conducted on a drive having a 4.0-in. diameter motor pulley, a 16-in. diameter driven pulley, 24-in. center distance, with an 1140-rpm motor giving a belt speed of 1200 ft per min. The horsepower was maintained constant, and total belt tension varied over a wide range to obtain different values of

Table 3. Horsepower Factors for Various Drives at 2% Slip

Type of Pulley	Belt	Horsepower Factor
Laminated wood, treated	Soft tan leather	95.5
Cast iron	Leather with dressing	95.0
Laminated wood, treated	Rubber fabric	92.0
Paper	Tan leather	91.0
Laminated wood, untreated	Soft tan leather	79.0
Cast iron	Soft tan leather	75.0
Paper	Rubber fabric	73.0
Laminated wood, untreated	Rubber fabric	71.5
Cast iron	Rubber fabric	68.0
Cast iron, glazed	Rubber fabric	55.0
Cast iron	Leather, oily	32.0

slip. The final performance is rated at 2% slip with a horsepower factor obtained from the formula:

$$\frac{T_1 - T_2}{T_1} \times 100 \tag{1}$$

where T_1 is tight side tension and T_2 is slack side tension. A perfect belt would be one in which the slack side tension reached zero, indicating a positive drive. Results of the tests are shown in Table 3.

CONE PULLEYS

Cone pulleys for driving machine tools should be so designed that the speeds will be in geometrical progression, that is, each speed is the product of the next lower speed and a constant multiplier. According to Carl G. Barth (*Am. Machinist*, Jan. 11, 1912), the ideal ratio of speeds is $\sqrt[4]{2} = 1.189$.

There are three general designs for cone pulley drives: (1) crossed belts; (2) open belts where the pulleys are so far apart that it is unnecessary to compensate for the tendency of the changing angle to alter the length of the belt; and (3) open belts with the pulleys so close together that the change in the angle tends to alter the length of the belt, which tendency must be compensated. Inasmuch as the length of the belt is constant in crossed belts and nearly so in open belts with long center distances, it is only necessary that the sum of the diameters of the corresponding steps on the mating cones be constant. In case 3, the length of the belt is a function of both the sum and difference of the diameters of the pulleys, and a simple solution is not possible. A large number of graphical methods for determining the diameters of the several steps of the pulleys are given in Halsey's *Handbook for Machine Designers*. However, a slight error in a graphical solution on a small scale may result in a serious error in the size of the pulleys, and a mathematical solution is preferable.

The equation for belt length (see page 15-51, eq. 12) may be written in the following form:

$$L_b = 2C + 1.571(r + 1)d + \frac{(r - 1)^2 d^2}{4C} \tag{2}$$

where L_b = length of belt, C = center distance between pulley shafts, d = diameter of smaller pulley, and r = ratio of diameter of larger pulley to that of smaller pulley = D/d. When the two pulleys are equal ($D = d = d_0$), the belt-length equation reduces to the simple form

$$L_b = 2C + 3.14d_0 \tag{3}$$

from which suitable preliminary values of L_b, C, and d_0 may be determined, in conjunction with the belt rating tables and formulas given on page 15-46. Having established belt length, center distance, and pulley ratio r at each step, the numbers may be substituted into eq. 2, which then reduces to a quadratic with unknown d, which may be solved by the standard formula

$$d = \frac{-b + \sqrt{b^2 - 4ac}}{2a} \tag{4}$$

where, in this case, $a = (r - 1)^2/4C$, $b = 1.571(r + 1)$, and $c = 2C - L_b$.

SPEEDS IN GEOMETRICAL PROGRESSION. If it is desired that the speed ratios shall increase by a constant percentage, or in geometrical progression, then $r_2/r_1 = r_3/r_2 = r_n/r_{n-1} = c$, a constant.

$$\frac{r_n}{r_1} = c^{n-1}; \qquad c = \sqrt[n-1]{\frac{r_n}{r_1}}$$

BELT DRIVES

By M. L. Price

16. THEORY OF POWER TRANSMISSION BY BELTING

GENERAL BELT FORMULA. Although many types of belts and pulleys are used for transmission of mechanical power, the same general principles are applicable to any particular combination.

Since a belt drive is fundamentally a friction drive, the most important factor involved is the relationship between belt tensions, which produce pressure between belt and pulley as well as the means of developing pulley torque, and friction coefficient.

For static conditions, friction coefficient f is used to define the limiting value of friction force F_f available to prevent sliding between two flat surfaces, and normal force N which holds the two surfaces together.

$$F_f = fN \tag{1}$$

Applied to the dynamic conditions and curved surfaces involved in belt drives, this very fundamental law of mechanics becomes

$$\frac{T_1 - T_c}{T_2 - T_c} = e^{f\theta} \tag{2}$$

in which T_1 is the tension, on the tight side of the belt, pounds; T_2 is the tension, on the slack side of the belt, pounds; T_c is the tension developed in the belt by centrifugal action, pounds; e is the base of the natural or Naperian logarithms, 2.71828; f is the friction coefficient between belt and pulley; and θ is the arc of contact between belt and pulley, radians.

The centrifugal tension T_c may be neglected for belt speeds below 2000 ft per min, in which the general equation becomes

$$\frac{T_1}{T_2} = e^{f\theta} \tag{3}$$

For belt speeds in the region from 3000 to 5000 ft per min, the centrifugal stress developed within the belt becomes an appreciable portion of the total working stress. Belt drives should not be designed to operate at belt speeds greater than 5000 ft per min without a very careful consideration of the centrifugal effect. The significance of the centrifugal tension term, T_c, is that a part of the gross tensions T_1 and T_2 is used up in forcing the belt to follow a curved path around the pulley and is thus not available to produce pressure between the belt and pulley.

The magnitude of the centrifugal tension is given by the formula

$$T_c = \frac{\rho b t V^2}{300g} \text{ lb} \tag{4}$$

where ρ is the density of the belt, pounds per cubic inch, usually taken as 0.035 to 0.045 for leather or fabric belts; b is the width of the belt, inches; t is the thickness of the belt, inches; V is the belt speed, feet per minute; and g is the gravitational constant, 32.2 ft per sec per sec.

The term, $e^{f\theta}$, in which θ is expressed in radians, may be transformed to the common logarithmic system and the use of arc of contact in degrees as follows,

$$e^{f\theta} = 10^{0.00758f\alpha} \tag{5}$$

The general belt formula may thus be interpreted as follows: The ratio of the available or effective belt tensions is the number whose common logarithm is $0.00758f\alpha$.

BELT TENSIONS. Equation 2 gives the limiting condition of effective or available tension ratio in terms of friction coefficient and arc of contact between belt and pulley. Design values for this ratio vary from 2 to 6, depending on the nature of the belt and pulley and on the arc of contact. Atmospheric conditions and degree of cleanliness of the drive should be taken into account when design belt tension ratios are selected.

The tension in the tight side strand of the belt should not be so great as to give a unit tensile stress greater than a safe design value. For leather belts, the design stress may be taken as 200 to 400 psi of belt section, based on an ultimate tensile strength of 2000 to 5000 psi and a joint strength of 50% for wire lacing to 100% for cemented joints.

The tension in the slack side strand of the belt should not be too low or the stability of the drive will be lost.

Sufficient tension may be provided by center distances of at least 20 to 25 ft and a reasonable belt sag, by weighted idler pulleys, pivoted motor bases, and spring loaded sliding bases, or, in the case of fixed center distances, by belt clamps and spring scales to insure sufficient initial tension when belts are made endless. One empirical formula used by many belt manufacturers states that the initial belt tension, to insure good drive conditions, should be about 36 lb per inch of width, per ply, per strand (tight and slack side). Thus, for a 4-in., double-ply leather belt, the correct total tension, $T_1 + T_2$, should be about 576 lb. Since the drive is so dependent on having sufficient belt tension to develop traction between belt and pulley, the use of some sort of automatic tensioning device is to be recommended wherever possible.

ARC OF CONTACT. The exponential function $e^{f\theta}$ gives the ratio of effective tensions under limiting conditions (eq. 2) and must be as high as possible in order to develop maximum difference in tension, $T_1 - T_2$, for maximum pulley torque.

It is desirable to have the arc of contact as near 180 degrees as possible and, except in very special cases, not less than 120 to 130 degrees. The arc of contact, expressed in degrees, is given by the expression

$$\theta = 180 \pm 2 \sin^{-1}\left(\frac{D - d}{2C}\right) \tag{6}$$

where D and d represent the diameters of the large and small pulleys, respectively, and C represents the center distance between pulley shafts. The minus sign is to be used in getting the arc of contact for the small pulley, and the plus sign is used for the large pulley.

FRICTION COEFFICIENT. A number of empirical relationships have been developed for the purpose of obtaining a design value for the friction coefficient under different operating conditions. However, none of the available formulas are adequate, since they do not take into account a sufficient number of variables. It is far safer to use values obtained by actual laboratory tests which have been carried on under conditions similar to those in the drive being designed.

Some of the factors influencing the friction coefficient are type and condition of pulley surface, type and condition of belt surface, cleanliness of surrounding air, temperature, humidity, belt speed, area of surface of contact between belt and pulley, thickness of belt compared to pulley diameter, and percentage of slip between belt and pulley as expressed in terms of belt speed.

For design purposes, the following friction coefficients may be used unless more specific values can be obtained by direct tests.

Table 1. Values of Friction Coefficient for Belt Drives

Pulley Material	Belt Material	Friction Coefficient
Cast iron or steel	Leather	0.40
Cast iron or steel	Rubberized canvas	0.25
Paper or wood (treated)	Leather	0.50
Paper or wood (treated)	Rubberized canvas	0.40
For very oily or wet conditions, any type of pulley or belt		0.15–0.20

17. HORSEPOWER OF LEATHER BELTS

THEORETICAL DESIGN. The general belt formula given in eq. 2 may be expressed in the following form:

$$(T_1 - T_2) = bt\left(s - \frac{\rho V^2}{300g}\right)\left(\frac{e^{f\theta} - 1}{e^{f\theta}}\right) \tag{7}$$

where the symbols are the same as those used in eqs. 2 and 4. Equation 7 gives the limiting friction force or tension difference available for producing pulley torque without an excessive amount of belt slip; it may be used either for determining the horsepower capacity of a given belt and pulley combination, or for the selection of a belt width for a given horsepower and drive pulley speed, and for an assumed belt thickness t and design stress s. The value of thickness of leather belts is given at the top of Table 3.

HORSEPOWER FORMULA. The horsepower capacity of a belt drive may be expressed in terms of the allowable value of the tension difference, as given by eq. 7, and the belt speed in feet per minute, as follows:

$$\text{Horsepower} = \frac{(T_1 - T_2)V}{33{,}000} \tag{8}$$

where V is found from eq. 9.

BELT SPEED. The speed of the belt, V ft per min, may be obtained by the formula

$$V = \frac{D}{12}\pi N \tag{9}$$

in which D is the pulley diameter in inches, π is 3.1416, and N is the pulley speed in revolutions per minute.

MANUFACTURER'S RATINGS OF LEATHER BELTS. In an attempt to simplify and standardize the selection of leather belts, the Engineering Committee of the American Leather Belting Association (ALBA) has issued copyrighted horsepower rating tables for oak-tanned flat leather belting used with electric motor drives. These tables (Tables 2, 3, 4, 5, and 6) are used as follows:

Table 2 gives the belt speed in feet per minute corresponding to the pulley diameter at its specified speed in revolutions per minute.

Table 2. Belt Speeds in Feet per Minute for Different Pulley Diameters and Revolutions per Minute

(American Leather Belting Assoc.)

Minimum Pulley Diameter, in.	Belts Under 8 in. Wide	3	5	6	8	12	20	24
	Belts 8 in. Wide and Over			8	10	14	24	30

These are the minimum allowable pulleys for the belts of the above thicknesses.

Note: For belt speeds of over 6000 ft per min, consult the leather belting manufacturer.

Table 4 shows motor-load correction factor M, which is dependent upon the starting characteristics of the electric motor used.

Table 4. Correction Factors M for Type of Motor and Starting Methods Used

(American Leather Belting Assoc.)

Motor Type and Starting Method	Correction Factor, M
Squirrel cage, compensator start	1.5
Squirrel cage, line start	2.0
Slip ring and high starting torque	2.5

Table 5 gives pulley correction factor P for the diameter of the smaller pulley.

Table 5. Correction Factors P for Diameters of Smaller Pulley

(American Leather Belting Assoc.)

Diameter of Small Pulley, in.	Correction Factor, P
4 and under	0.50
4 1/2 to 8	0.60
9 to 12	0.70
13 to 16	0.80
17 to 30	0.90
Over 30	1.00

Width or horsepower rating of belt are found from the formulas

$$b = \frac{R \times M}{K \times P} \tag{10}$$

$$\mathrm{HP} = \frac{b \times K \times P}{M} \tag{11}$$

where b = width of belt, inches; R = name-plate horsepower rating of electric motor; HP = horsepower rating of belt; M = motor-load factor, Table 4; K = theoretical belt capacity factor, Table 3, and P = pulley correction factor, Table 5.

For special operating conditions, multiply the belt width given by eq. 10 by a factor F selected from Table 6.

Table 6. Correction Factors F for Special Operating Conditions

(American Leather Belting Assoc.)

Operating Conditions	Factor F
Oily, wet, or dusty atmosphere	1.35
Vertical drives	1.2
Jerky loads	1.2
Shock and reversing loads	1.4

Example 1. Squirrel cage induction motor rated 15 hp at 1750 rpm, across the line starting. Motor pulley, 8 in. in diameter; driven pulley, 16 in. in diameter. Required: thickness and width of belt to be used for this drive.

Solution. Belt speed is 3665 ft per min, as determined from Table 2. Belt thickness is medium double, which is suitable for 8-in. diameter pulley, as determined from bottom of Table 3. Belt capacity factor K is 10.2, as determined from Table 3 by interpolation. Motor correction factor M is 2.0, as determined from Table 4. Pulley correction factor P for 8-in. diameter pulley is 0.60 from Table 5. From eq. 10

$$b = \frac{R \times M}{K \times P} = \frac{15 \times 2.0}{10.2 \times 0.6} = 4.9 \text{ in.}$$

Use a medium double belt 5 in. wide unless special operating conditions exist, in which case the width should be increased by the factor indicated in Table 6.

Example 2. Determine the horsepower rating of an 8-in. heavy double leather belt operating between a 48-in. diameter cast-iron pulley mounted on a line shaft turning at 200 rpm and a 16-in. diameter cast-iron fan pulley turning at 600 rpm. The drive is horizontal and the atmosphere is dusty.

Solution. Belt speed may be determined from Table 2 by simple proportion. The belt speed for a 16-in. pulley and 435 rpm is 1824 ft per min. At 600 rpm, the belt speed would be

$$\frac{600}{435} \times 1824 = 2515 \text{ ft per min}$$

Belt capacity factor K from Table 3, corresponding to a belt speed of 2515 ft per min and heavy double leather belt, is 8.6 hp per inch of width. Pulley correction factor P for a 16-in. pulley is 0.80, as obtained from Table 5. Special operating condition factor F for dusty atmosphere is 1.35, as shown in Table 6. Horsepower rating, as given by eq. 11, is

$$Hp = \frac{b \times K \times P}{M \times F} = \frac{8 \times 8.6 \times 0.80}{1.0 \times 1.35} = 40.8$$

18. FLAT FABRIC AND RUBBERIZED CANVAS BELTS

FABRIC BELTS. Although leather has for many years occupied a position of prominence in the field of flat belting, woven fabric belts of one type or another also are used in many applications and many special claims are made for them. Most of these fabric belts are fabricated from woven cotton duck or canvas, although several types of hair belts, known generally as camel's hair, are used. Most fabric belts are made up of layers of woven material and are held together and protected as well as "frictionized" by means of gums, rubber, or synthetic resins.

STITCHED CANVAS. Belts made up of layers of canvas duck to provide sufficient strength and thickness and held together by stitching are inexpensive for applications where little protection against moisture and oil is required. The friction coefficient is low, usually about 0.20, but the resistance to higher operating temperatures is good.

Because of low friction, care must be exercised so that machine bearing pressures are not excessive.

Stitched canvas belts are made of 24- to 48-oz. duck, with from 3 to 12 plies, and in widths from 1 to 60 in.

Strength of stitched canvas belts compares favorably with a leather belt of equivalent thickness and width, but the horsepower capacity must either be reduced considerably because of lower friction coefficient, or higher total belt tensions must be employed. (See eq. 7.)

Stitched canvas belts are sometimes made moisture resistant by painting them with moisture-proofing compounds.

RUBBERIZED CANVAS BELTS. Several methods are used in the fabrication of rubberized canvas belts. In nearly all, the individual layers of duck are first impregnated under pressure with a slow-aging rubber or synthetic rubber compound. Desired belt thickness is built up either by building one layer on another, followed by vulcanization and slitting to proper width, or by folding and vulcanizing under pressure. The latter method provides smooth edges. Tension or load-carrying cords are often employed to reduce stretch and to increase strength. Such cords usually are of prestretched cotton, rayon, glass, or flexible steel-wire rope.

Rubberized canvas belts have the advantage of high resistance to moisture, oil, and higher operating temperatures. The main disadvantage of this type of belt lies in the low coefficient of friction after the surface coating of rubber has been worn down to present a smooth glazed surface on the canvas. Higher traction can be provided with paper or wood pulleys which have been impregnated and surface-coated with compounds of highly viscous nature.

BALATA BELTING. Canvas belts are sometimes impregnated with balata gum, similar to gutta-percha, obtained from trees in South America. These belts have high resistance to moisture and animal oils but do not stand up under action of mineral oils or temperatures above 120 F. The strength of balata belting depends on the canvas and its method of fabrication so that the horsepower capacity is about the same as for rubberized belts.

HORSEPOWER RATING OF CANVAS BELTS. Published tables vary considerably regarding horsepower capacity of canvas and rubberized canvas belting. It must be kept in mind that the coefficient of friction between worn rubberized canvas and cast-iron or steel pulleys is considerably less than that for leather and cast-iron or steel. Greater total belt pull is therefore required for the transmission of a given amount of power and pulley diameters, and care must be taken to prevent overloading of bearings.

Table 7. Horsepower Rating of Rubberized Canvas Belting, per Inch of Width

(180-degree arc of contact)

(Reprinted from *Power*, Feb. 1937, by permission)

No. of Plies	Belt Speed, ft/min									
	1000	1500	2000	2500	3000	3500	4000	4500	5000	5500
3	1.2	1.8	2.4	2.9	3.5	4.0	4.3	4.6	4.9	5.2
4	1.7	2.5	3.2	4.0	4.7	5.4	5.8	6.2	6.6	7.0

12	5.3	7.8	10.3	12.8	15.0	17.2	18.6	20.0	21.2	22.3

The largest possible pulley diameters allowed by space limitations should be used so as to reduce required effective belt pull or friction force. Table 7 gives representative horsepower ratings for regular rubberized canvas belts not having special cord or wire rope reinforcement.

SELECTION OF BELT. After pulleys have been selected to give correct speed ratio, using the largest pulleys consistent with space limitations and a belt speed that does not exceed 5000 to 6000 ft per min, consult Table 8 for a tentative selection of number of plies. From Table 7, obtain horsepower rating corresponding to number of plies and belt speed. Compute arc of contact by eq. 6, and obtain correction factor from Table 9. Multiply horsepower rating by correction factor. Divide peak or starting horsepower to be transmitted by corrected horsepower rating to get required width of belt. If required width does not agree favorably with the values listed in Table 10, repeat the selection, using either more or less plies as needed.

Table 8. Minimum Recommended Pulley Diameters for Rubberized Canvas Belts Operating at Different Speeds

(Reprinted from *Power*, Feb. 1937, by permission)

	Belt Speed, ft/min		
	Under 2000	2000–4000	Over 4000
No. of Plies	Minimum pulley diameter, in.

12	4	7	36	7	12
14	5	8	42	7	12

19. BELT INSTALLATION AND MAINTENANCE

PULLEY ALIGNMENT. Great care should be exercised to see that pulleys and shafts are in correct alignment. Shafts should be parallel, and edges of pulleys should be lined up with a straightedge or strings.

BELT LENGTH. The best way to determine the correct length of belt is by a steel tape wrapped around the pulleys.

If belts are to be spliced and cemented, an additional amount of belt length must be provided for making the lap.

If the center distance between pulley shafts cannot be adjusted, the correct initial belt tension can be provided by subtracting from $^1/_{16}$ to $^1/_8$ in. per foot of belt length, depending on the stretchiness of the belt material. The exact amount to be subtracted must be determined by experience or can be predicted by the belt manufacturer.

Several formulas have been developed for those cases where it is impossible to determine belt length by direct measurement, but the formula now in almost universal use is

$$L_b = 2C + 1.571(D + d) + \frac{(D - d)^2}{4C} \qquad (12)$$

where L_b = length of belt, C = center distance between pulley shafts, D = diameter of larger pulley, and d = diameter of smaller pulley.

It is recommended that all dimensions be in inches and that the length of belt be given in inches when ordering from a manufacturer or distributor. Also state whether the belt is to be made endless, whether the allowance for the splice has been provided, and whether the manufacturer is to deduct enough belt to provide initial tension.

BELT JOINTS. Belt manufacturers strongly recommend that endless belts be used wherever possible. Leather belts which have been spliced and cemented by use of a high quality waterproof cement will be just as strong at the joint as in the rest of the belt. Some applications require some sort of lacing so that the ends of the belt may be quickly joined together whenever the belt must be shortened to take care of stretch. The oldest form of lacing consists of rawhide strips which are passed through holes punched in the ends of the belt. Although this form of lacing produces a safe and flexible joint, strength is sacrificed.

Rubberized canvas belts may be made endless by splicing and vulcanizing for maximum strength and smoothness of joint.

Either leather or rubberized canvas belts may be joined by a wide variety of wire or metal hooks, clips, clamps, and plates. All the various methods for lacing belts reduce the net strength of the belt joint, and certain types introduce a real safety hazard. Belts jointed by metal lacing should be surrounded by guards.

BELT DRESSING. Most manufacturers of leather belting introduce various oils and greases into new belts to lubricate the leather fibers and to control flexibility. In some cases, other compounds are incorporated to increase friction coefficient. If sufficient tension is provided and if the belt and pulley surfaces are kept clean, little need exists for the dressing of a belt to make it pull properly. When a belt slips excessively, the chances are that the tension is not sufficient or that the belt has become caked with oil, grease, or dirt. Belts should be regularly cleaned with a mixture of carbon tetrachloride and unleaded gasoline, in the proportions of from 25% to 50% carbon tetrachloride. After such a cleaning, at intervals ranging from 3 months to a year, depending upon operating conditions, type of service, and atmospheric conditions the belt should be dressed with a dressing obtained from a reputable belt manufacturer. Good dressings are those designed primarily for the lubrication of the belt fibers. Resinous dressings of a tacky nature should be avoided; they are unnecessary if proper tension is provided and they do not provide the proper lubricating action.

Dressing should be applied uniformly but sparingly so that no excess dressing remains on the belt and pulley surfaces.

20. ARRANGEMENT OF BELT DRIVES

At one stage in the development of our machine age, most power was transmitted by long line shafts and many belts and pulleys. Quarter-turn drives were very common, and special arrangements to take care of nonintersecting shafts were often required. This type of drive is not so common today, and the following discussion is considerably condensed. More complete coverage of guide pulleys, quarter-twist belts, and mule pulley stands will be found in the 11th edition of Kent's *Mechanical Engineers' Handbook, Design and Shop Practice* volume.

ARRANGEMENT OF PULLEYS. If possible, machinery driven from overhead shafting should be so arranged that the belt will make an angle from the vertical of not less than 45 degrees. Never, unless it is absolutely impossible to avoid it, should driving and driven pulleys be in the same vertical line. Care should be taken to arrange the pulleys in line with each other, the tops of the crowns being aligned. Otherwise the belt will tend to stretch unevenly and to run crooked. Machinery should be so placed that the tight strand of the belt will be the bottom strand. However, if machines are so placed that the pull of the belts at alternate line-shaft pulleys is in opposite directions, the wear and strain on bearings will be reduced. This arrangement of machinery will make one-half of the belts drive with the top strand tight.

The distance between shafts has considerable influence on the life of belts. Distances should, as a rule, be made as great as possible up to reasonable limits. For narrow belts on small pulleys, a good average figure is 15 ft; for larger belts, the center-line distance should be from 20 to 25 ft; and for main belt drives using wide and heavy belts, pulleys should be from 25 to 30 ft apart. If the distance is made too great the belt will have a tendency to flap and injure itself.

IDLER PULLEYS. Belts which are run on pulleys located close together are liable to stretch rapidly and thus lose the tension necessary to the transmission of the desired amount of power. For such cases, and also for belts which are required to run for long periods without stopping, an idler pulley, which can be moved against the belt to take up the slack and thus increase the tension, will be found desirable. The idler should be located about one-quarter of the distance from the driving pulley and should bear against the slack side of the belt. It increases not only the tension but also the arc of contact. The idler may be so constructed that it can be moved against the belt at will, or it may act automatically by means of a spring or gravity. Such an arrangement is shown in Fig. 1.

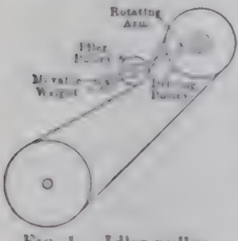

Fig. 1. Idler pulley.

GUIDE PULLEYS. Where two shafts that are not parallel and that do not intersect are to be connected by belting, and the conditions are such as to make a quarter-twist belt inadvisable, guide pulleys are used (Fig. 2). The function of the guide pulley is to alter the direction of the belt and cause it to run squarely on to the receiving pulley. The location of the guide pulley with reference to the main pulleys is determined by the intersection *CD* of the planes passing through the center of the face of the main pulleys and perpendicular to their axes. The guide pulleys should be located at the intersection of the tangents *HE* and *EJ* and *FG* and *FK*, respectively, and the plane through the center of the face of each pulley should coincide with the planes formed by these tangents. Other arrangements will suggest themselves according to the needs of each particular case. It is only necessary to observe the precaution that the guide pulleys be so placed that they will receive the belt squarely from the main pulley and deliver it squarely to the next one. If this is done, the pulleys may be placed in practically any location and at practically any angle.

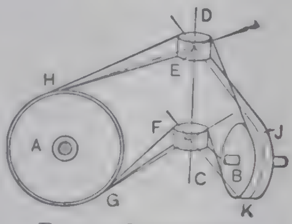

Fig. 2. Guide pulleys.

QUARTER-TWIST BELTS. One of two shafts at right angles to each other and in different planes may be driven from the other by means of a belt with a quarter twist in it, providing that the distance between the shafts is not too short. The belt must run squarely on to each pulley, and the point at which the belt leaves each pulley must lie in the straight line formed by the intersection of the planes passing through the center line of the face of each pulley and perpendicular to their axes, as shown in Fig. 3. The driving pulley is *AD*, and the belt runs in the direction shown by the arrows. The point *C* at the end of the horizontal diameter of the driven pulley at which the belt leaves it is set so that it is vertically above the point *A* at the end of the horizontal diameter of the driving pulley where the belt leaves that pulley. The quarter-twist has been used with belts as wide as 30 in. There should be a considerable distance between the shafts, however. For heavy belts and short center-line distances, guide pulleys or mule pulley stands should be used. **A quarter-twist belt will drive in one direction only.**

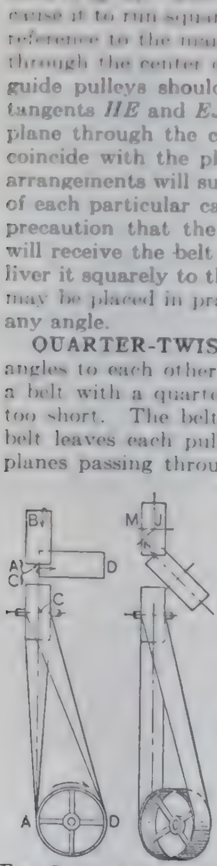

Fig. 3. Quarter-twist belt.

Quarter-twist belts may be used to drive shafts which make angles with one another of other than 90 degrees, if the rule is observed that the points at which the belt leaves the pulleys are in the straight line determined as explained previously.

MULE PULLEY STANDS. A common arrangement of guide pulleys, known as a mule pulley stand, is shown in Fig. 4. If it be borne in mind that the governing principle of mule pulley drives, and in fact of all drives where the belt joins two pulleys that are not in the same plane, is that the belt must be delivered squarely on the pulleys, but that it can leave them at any angle within reasonable limits, it is evident that the mule pulleys can be placed in any location desired. If local conditions make it advisable, the mule pulleys can be so placed as to require the belt to leave either or both of the main driving pulleys in a horizontal position. The method of laying out the drive is the same in any event.

The fact that it is possible to vary the position of the mule pulleys without affecting the working of the drive makes it possible to place both mule pulleys on the same shaft.

With reference to Fig. 4, if the belt travels in the direction of the arrows, it is evident that, if the lower mule pulley be moved in the direction that the belt travels, the belt will still be delivered squarely to pulley *B*. It will, of course, leave pulley *A* at an angle, but this will have no effect if the mule pulley is maintained at the same angle as before, since the belt will still be received squarely by the mule pulley. If the distance between the axes of the mule pulley shafts is not excessive, the lower mule pulley may be moved until the two shafts are in line, as regards the elevation. They will, however, still be out of line as regards the end view. By the same process of reasoning as before, however, it is evident that the upper mule pulley can be similarly moved in the direction of the belt travel until its axis is in line with that of the lower pulley in the end view. The axes of the two mule pulleys then will coincide, and in their new locations they can be mounted on the same shaft.

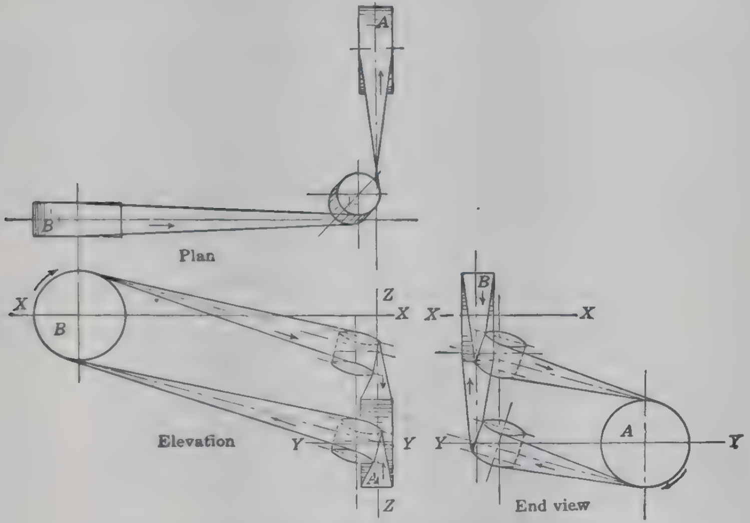

FIG. 4. Mule pulley drive.

The foregoing considerations apply to drives where the main pulleys are of the same diameter. If the diameters are unequal, the shafts of the mule pulleys will lie at different angles and the pulleys must be mounted on separate shafts.

21. V-BELT DRIVES

By H. A. Wilson

The V-belt drive consists of one or more endless belts constructed of cords (cotton, rayon, synthetic, or steel) and fabric impregnated with and embedded in rubber, and of trapezoidal cross section. The belts run on sheaves which have V-shaped grooves on the periphery. The angle of the groove depends on the size of the sheave and on the service in which the belt is to be used. Manufacturers of V-belts should be consulted concerning details of a particular drive.

The drives are so designed that the belt is approximately flush with the top of the groove. A clearance is provided at the bottom of the grooves in the sheaves to insure contact with the belt only on the sides of the grooves. These drives will run in either direction with slack either on top or bottom strands. They are especially adapted to reversing service.

The V-belt was first developed by the Allis-Chalmers Manufacturing Company whose product is sold under the name of Texrope Drives. Other manufacturers are Dodge Manufacturing Corporation, Mishawaka, Ind.; Worthington Pump and Machinery Corporation, Buffalo, N. Y.; The American Pulley Company, Philadelphia, Pa.; and T. B. Woods's Sons Company, Chambersburg, Pa. Belts are manufactured by B. F. Goodrich Company, Akron, Ohio; Gates Rubber Company, Denver, Col.; Dayton Rubber Company, Dayton, Ohio; and Goodyear Rubber Company, Akron, Ohio.

OPERATION. In the operation of V-belt drives, it is important to maintain proper alignment. The driving and driven shafts should be parallel, and the V-belts should be at right angles to the shafts. Every V-belt drive installation should include some method of adjusting tension on the belts. This can be accomplished by an adjustable base where electric motors are used, or by an idler arrangement when it is impossible to provide adjustment otherwise. Idlers should preferably operate on the inside of the V-belt.

V-belt drives should not be operated at temperatures in excess of 160 F. *Standard* V-belts should be protected from oil. *Special* oil-resisting V-belts are available for drives which must operate under conditions where oil may come in contact with the belts. Special belts are also available for installation where static charges built up on the belts must be dissipated. Belt dressing should never be used on any V-belt drive. V-belts should be stored in a cool, dry place, protected from light. When a V-belt drive requires replacement of belts for the first time, a complete new set should be installed; the belts which are still in good condition can then be used as future replacements.

BELT SIZES. Standard V-belts are manufactured in five different cross sections and various lengths. Table 11 shows the cross section dimensions, serial number, and pitch length of the belt.

Table 11. Standard V-belts

HORSEPOWER RATING. Selection of a V-belt drive to transmit power economically and satisfactorily depends on the proper consideration of the maximum load to be transmitted and the characteristics of the component machines. Service factors have been developed (Table 17) to aid in the selection of the proper drive.

The horsepower tables (Tables 12 to 16) list the power transmitted by one belt with velocity and sheave size as the determining factor in power transmitted.

(Continued on p. 15-60)

Table 12. Horsepower Ratings for Section A V-belts

SERVICE FACTORS FOR V-BELT DRIVES. The horsepower ratings (Tables 12 to 16) are maximum ratings. Since V-belts are used on every type of machinery, conditions may exist which cannot be covered by horsepower ratings. For that reason the service factors (extra drive capacity) in Table 17 should be used. This extra capacity should be above the name-plate rating of the motor.

Table 17. Service Factors

Agitators, paddle-propeller	1.0–1.2
Bakery machinery	1.0–1.2
Brick and clay machinery	1.2–1.6
Compressors	1.2–1.4
Conveyors	1.0–1.6
Crushing machinery	1.4–1.6
Fans and blowers	1.2–2.0
Flour-feed and cereal mill machinery	1.0–1.4
Generators and exciters	1.2
Laundry machinery	1.2
Line shafts	1.4–2.0
Machine tools	1.0–1.4
Mills	1.4–1.6
Oil-field machinery	1.2–1.6
Paper machinery	1.2–1.6
Printing machinery	1.2
Pumps	1.2–2.0
Rubber plant machinery	1.4–2.0
Screens	1.2–1.4
Textile machinery	1.2–1.8

SELECTION of a V-belt drive should be based on nature of the load, type of driving unit, horsepower rating, and speeds of driving and driven units. To obtain the horsepower capacity for the drive, multiply the rated horsepower (name-plate rating) of the driving unit by the recommended service factor (Table 17). From Table 18 select the belt section to be used. Sheave diameter should not be less than the recommended minimum diameter (Table 19) for maximum life of belts. Correction for arc of contact on small

Table 18. General Belt Selection Table

Motor Horsepower	Motor Speed, rpm				
	1800	1200	900	720	600 and below
1/2–3/4	A	A	A		
1–1 1/2	A	A	A		
2–3	A or B	A or B	A or B	A or B	
5	A or B	A or B	A or B	B	
7 1/2	A or B	A or B	B	B or C	B or C
10	A or B	B	B	B or C	C
15	B	B or C	B or C	C	C
20	B or C	C	C	C	C
25	C	C	C	C	C
30	C	C	C	C	C
40	C	C or D	C or D	C or D	D
50	C	C or D	C or D	D	D
60	C	C or D	C or D	D	D
75	C	C or D	C or D	D or E	D or E
100	C	D	D	D or E	D or E
125		D	D	D or E	D or E
150		D	D	D or E	E
200		D	D	E	E
250 and over				E	E

Note: When two cross sections are shown: If sheave pitch diameters are limited, use the smaller cross section. If sheave face widths are limited, use the larger cross section. If there are no limitations, use cross section providing the most economical drive.

sheave is determined from Table 20, the arc being given by the approximate formula:

$$\text{Arc of contact} = 180 - \frac{(D - d)\,60}{C}$$

Table 19. Minimum Sheave Sizes

Belt Section	Minimum Recommended Pitch Diameter, in.
A	3.0
B	5.4
C	9.0
D	13.0
E	21.0

where D = diameter of large sheave, inches; d = diameter of small sheave, inches; and C = center distance of drive inches. See Table 20 for correction factors. Belt velocity should be held under 5000 ft per min.

Table 20. Correction Factors Corresponding to Various Degrees of Contact on the Small Sheave

Arc of Contact, degrees	Correction Factor	Arc of Contact, degrees	Correction Factor
180	1.00	130	0.86
170	0.98	120	0.83

CENTER DISTANCE. If the sheave sizes required for a drive and the approximate center distance are known, the belt length can be estimated by the approximate formula

$$L = 2C + \frac{\pi}{2}(D + d)$$

Select the nearest belt length from Table 11.

The center distance can be calculated from the formula

$$C = \frac{L - \left[\frac{\pi}{2}(D + d) + \frac{(D - d)^2}{L}\right]}{2}$$

For small ratios and long centers, reasonably accurate centers can be found by the formula

$$C = \frac{L - 1.57(D + d)}{2}$$

The pitch length of the belt given in Table 11 is used in all calculations.

Example. A fan operating continuously at 525 rpm is to be driven by a 15-hp 1750-rpm motor. Center distance is approximately 36 in. From Table 18, a B belt is recommended for this drive. Table 17 shows service factor of 1.2 to 2.0. For continuous operation with squirrel cage motor, the service factor will be 1.6. Horsepower of drive will be 1.6 × 15 = 24.0 hp. Speed ratio 1750/525 = 3.33. Sheave sizes of 6 and 20 in. will give the desired ratio, and 6 in. is above the minimum for B belts. Sheaves are stock sizes (consult manufacturer's catalog for stock sizes). Belt length $L = 2C + (\pi/2)(D + d) = 112.8$. Belt required is B112, length of which is 114 in. (Table 11). The center distance will be found to be 36 in. Belt velocity will be 2745 ft per min. From Table 13, the horsepower per belt = 3.6. Correcting for arc of contact on small sheave, correction factor = 0.94. Corrected horsepower = 0.94 × 3.6 = 3.38. Number of belts = 24/3.38 = 7.1. Therefore, the drive would have 8 belts.

V-FLAT DRIVES, in which a small grooved sheave is used with a large flat pulley and a set of V-belts, are most successful when the following conditions are satisfied. (1) The speed ratio is 3 to 1 or more. (2) The center distance is less than the diameter of the large pulley. Centers three-fourths the diameter of the large pulley are desirable and should not exceed $1\frac{1}{2}$ times the diameter of the large pulley. (3) The large pulley has a flat face (no crown). (4) The face width of the flat pulley is at least 1 in. wider than the face width of the grooved sheave. For large drives a 10% increase in face width should be used. Face widths of grooved sheaves are given in Table 21.

Flat pulleys of cast iron or pressed steel are generally used. If crown face pulleys are used, there will be unequal tension between the center and outer belts, which may cause the belts to "crowd" toward the center of the crown.

Selecting a V-flat Drive. Use the correction factors for arc of contact in Table 22. The pitch diameter of the flat pulley (for calculation purposes) is found by adding to the diameter of the flat pulley the amount shown in Table 23. All other data required are the same as for a V-belt drive.

QUARTER-TURN DRIVES are used to transmit power from a horizontal shaft to a vertical shaft, or vice versa. Speed ratios should not exceed 2 $^1/_2$ to 1. Horsepower ratings of belts are 75% of those listed in Tables 12 to 16. The arc of contact correction factor is disregarded. The center distance should not be less than $5(P + W)$, where P = pitch diameter of larger sheave, inches, and W = face width of large sheave, inches. The center line of the horizontal shaft should be half the diameter of the large sheave above the center line of the vertical shaft, and the vertical shaft should be offset half the diameter of the small sheave. Special deep-groove sheaves are required. Face widths of deep-groove sheaves are given in Table 24.

SHORT-CENTER BELT DRIVES

By Philip G. Rhoads

Belt drives with flat belts, between shafts whose center lines are but a short distance apart, usually prove unsatisfactory unless provision is made to increase the tension in the belt, give a greater arc of contact, or increase the grip of the belt on the driving pulley. Increased tension and greater arc of contact may be obtained by a weighted floating idler (Fig. 1, p. 15-52). Increased tension which automatically adjusts itself to the load is obtained by means of a pivoted motor base (Figs. 6 and 10). The design shown in Fig. 14 adds the elasticity of springs in the base to the elasticity of the belt, thereby absorbing minor changes in belt length without introducing as much belt creep as would occur if the belt were made very elastic. V-rubber belt drives offset the low coefficient of friction of rubberized cotton on cast iron or steel by using the belt tension to wedge the belts into grooves and by using the expansion of the portion of the belt in compression, where bent, to bind the belts in the grooves. Good grip of flat leather belt on pulleys is obtained by use of fiber pulleys, special tanned belts, and proper belt dressing.

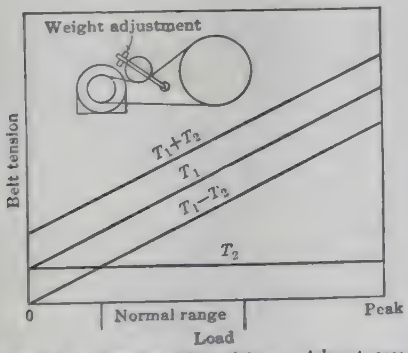

FIG. 1. Gravity idler drive. *Advantages:* Easy initial tension setting. Good automatic adjustment with load. Good automatic belt take-up. Good arc of contact. *Disadvantages:* Reverse bend in belt shortens belt life. Additional running bearing adds maintenance difficulties. Alignment difficult to maintain. Limited to rotation of motor in one direction.

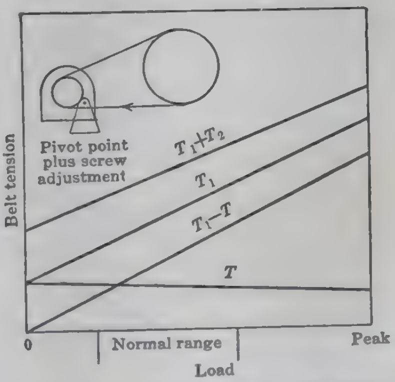

FIG. 2. Econ-O-Matic base. *Advantages:* Good automatic tension adjustment with load. Limited automatic belt take-up. Moderate maintenance. Easy adjustment for alignment. *Disadvantages:* Change in belt length affects tensions substantially. Limited to rotation of motor in one direction.

The accompanying charts, Figs. 1–5, show characteristic changes in belt tensions with changes in load for different types of short center drives. All charts give the same tension characteristics at peak load, which is the load for which the drive must be designed. Lowered tensions at normal and fractional loads are favorable to long belt and bearing

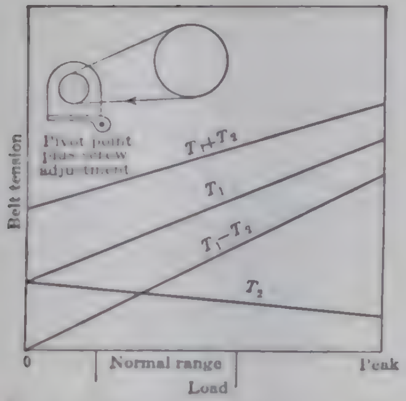

FIG. 3. Rockwood base. *Advantages:* Fair automatic tension adjustment with load. Good automatic belt take-up. Easy maintenance. Easy adjustment for alignment. *Disadvantages:* Inadequate tension available for some steep angle drives. Limited to rotation of motor in one direction.

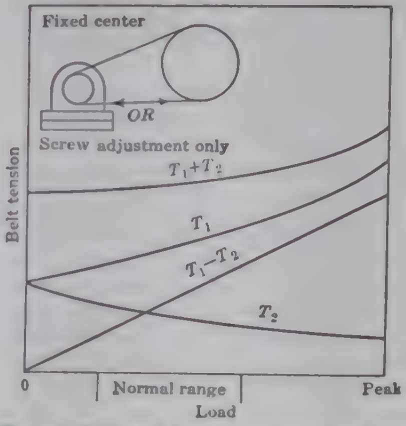

FIG. 4. Slide-rail base. *Advantages:* Easy installation. Motor can rotate in either direction. *Disadvantages:* No automatic tension adjustment except from elasticity of belt. No automatic belt take-up.

life and greater drive efficiency. Each method has characteristic advantages and disadvantages. The following notation is used: T_1 = tight side belt tension, pounds; T_2 = slack side belt tension, pounds; $T_1 - T_2$ = effective belt tension; and $T_1 + T_2$ = total belt tension.

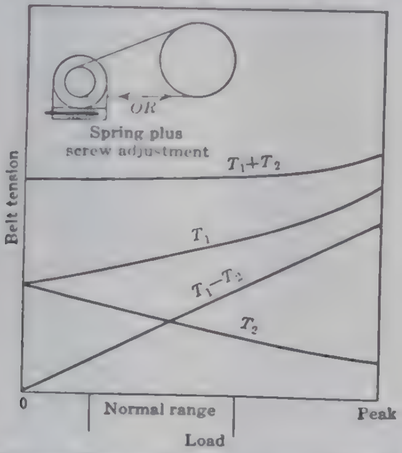

FIG. 5. Automatic base. *Advantages:* Easy application of initial tension. Easy adjustment of tension after installation. Moderate automatic belt take-up. Motor can rotate in either direction. *Disadvantages:* Sacrifices some of automatic tension adjustment from belt elasticity. Larger than necessary tension at light and normal loads.

22. PIVOTED MOTOR DRIVES

Pivoted motor-base drives are applicable for transmitting power through belts on short centers from motor to machine or counter shaft. The motor may be mounted on machine, floor, wall, or ceiling.

THE ROCKWOOD MOTOR BASE, made by the Rockwood Manufacturing Company, Inc., Indianapolis, Ind., replaces the usual slide rails and consists of a cast-iron or welded structural-steel base, a pivot shaft, and overhanging arms. (See Fig. 6.) The motor is mounted on the arms and is free to rotate to a limited extent on the pivot shaft. The overhang is adjustable and is set so that the weight of the motor maintains the correct belt tension irrespective of small changes in belt length, as caused by changes in load, centrifugal tension, changes in humidity, or permanent belt stretch.

Figure 7 shows the arrangement of base for various mountings. Note that the pivot shaft is near the tight strand of the belt. When so placed, the belt tension automatically increases with increased load on the motor and continuously adjusts itself to the load, relieving belt and bearings from peak tensions that are needed only for momentary peak loads or when starting.

Standard base sizes are available for common NEMA motor sizes. Semistandard bases are built for two and three bearing motors up to 400 hp. Bases of special design are available for ceiling mounting, Fig. 7*a* and mounting the motor above the driven pulley, Fig. 7*b*. There are also bases of special design for loom drives, spinning frame drives, agricultural drives, fractional hp motors, and other special services.

Rockwood bases can be advantageously used with V-rubber and flat rubber belts but are used more extensively with flat leather belts. Belts and pulleys should be selected as for a fixed center drive with proper consideration for maximum torque of motor, minimum pulley diameters, atmospheric conditions, and load characteristics. See Article 17 in this section on Horsepower of Leather Belts.

Correct belt tension is the minimum tension at which the belt will transmit the peak load without excessive slip. On pivoted motor drives the tension in the belt is regulated by the overhang of the motor. Instructions for adjusting the overhang by trial may be obtained from the manufacturers.

FIG. 7. Alternative mounting arrangements of Rockwood motor base.

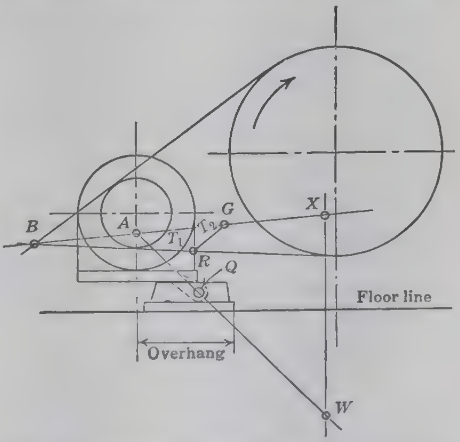

FIG. 8. Graphical determination of overhang on Rockwood motor base.

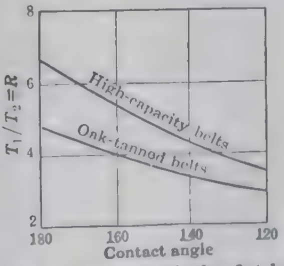

FIG. 9. Tension ratio for flat belts.

The required overhang for any drive may also be obtained by the graphical method shown in Fig. 8. The dimensions of the motor, motor base, and pulleys, the weight and speed of the motor, the peak load to be transmitted, and the limiting safe belt tension ratio are the data required. For safe practice, peak load $P = 1.5 \times$ motor name-plate rating for reduced-voltage starting, and $2.5 \times$ motor name-plate rating for line-start motors. Calculate the belt speed V (ft per min). Calculate T_1 and T_2 from the equations:

$$T_1 - T_2 = \frac{P \times 33{,}000}{V}$$

$$\frac{T_1}{T_2} = R = \text{Limiting tension ratio (see Fig. 9)}$$

$$T_2 = \frac{P \times 33{,}000}{V(R-1)}$$

$$T_1 = RT_2$$

Lay out the side view of the drive to any convenient scale. First draw the floor, wall or ceiling line on which the base is to be mounted. Show any posts, pipes, etc., which limit the location of the drive. Extend the lines of the belt strands to their point of intersection B.

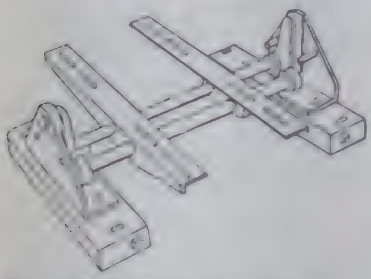

Fig. 10. Econ-O-Matic motor base. (Courtesy of American Pulley Co.)

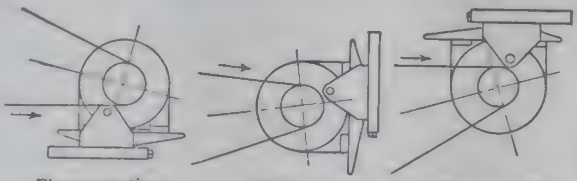
Note. When the pulleys are of nearly equal diameter, the belt strand lines may intersect beyond the paper. In this case, the resultant tension may be assumed to be $T_1 + T_2$. A practical solution for the location of the resultant is to divide the chord between the points of tangency of the belt on each pulley equal to the ratio of T_1 and T_2 with the point of division nearest T_1. Draw a line through these points and lay off $T_1 + T_2$ to scale on this line.

From this point of intersection B, using an engineer's scale, lay off $BR = T_1$ to any convenient decimal along the tight strand. At R, lay off $RG = T_2$ parallel to the slack strand, using the same scale as before. Draw and scale the resultant belt tension BG.

Drop a vertical line from the center of the motor pulley and find its intersection at A with the resultant belt tension line BG; prolong BG to X, making $AX = BG$.

At X, lay off the motor weight equal to XW vertically downward, using the same scale. Draw the diagonal from W to A.

Draw a horizontal line at the level of the pivot shaft. Its intersection Q with the diagonal WA locates the desired position of the pivot shaft, and the overhang is the scaled horizontal distance from Q to the vertical line through the motor pulley.



Floor mounting Wall mounting Ceiling mounting

Fig. 11. Alternative mountings of Econ-O-Matic motor base.

THE ECON-O-MATIC MOTOR BASE* is illustrated in Fig. 10. Its only moving element is a "cradle" made up of cast- or forged-steel cranks, solid-steel cross rods, and pressed-steel motor base arms, on which the motor is mounted. This "cradle" is pivoted in bronze bearings of the ball-and-socket self-aligning type except in the two smallest sizes in which plain bearings are used.

By utilizing the reverse torque action of the motor, it is possible, by selection of the proper motor pulley, pivoted base, and motor, not to require any initial tension on the belt and to have exactly the required tension at full or peak load. This is an ideal condition which is not actually realized in practice. In normal installations an initial belt tension of about 15% of the peak load tension is required.

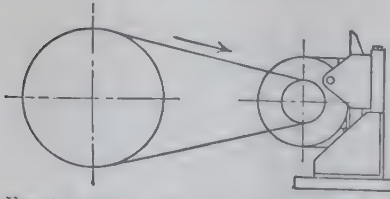


Fig. 12. Tight-side-top mounting of Econ-O-Matic motor base.

The standard Econ-O-Matic motor base shown in Fig. 10 can be utilized for floor, wall, and ceiling mounting as shown in Fig. 11. Note that in each mounting the direction of rotation is such that the tight side of the belt is closest to the pivot point of the motor base. Because reaction torque provides the greater portion of the belt tension, it is necessary that reaction torque work to increase the tension rather than to decrease it. When the tight side of the belt is away from the pivot point, the effect is for the reaction torque to decrease the belt tension with increase in load rather than to increase it. In applications requiring the tight side of the belt on top, it is necessary to employ the base shown in Fig. 12 which is called a tight-side-top base in which the pivot is carried above the motor pulley rather than below it and which fulfills the requirement that the pivot be closest to the tight side of the belt.

---

* Contributed by W. A. Williams.

On vertical downdrives, a special base is required to provide initial tension against the weight of the motor. This is accomplished by a base equipped with longer arms and a counterweight which overcomes the weight of the motor and provides initial tension adequate for the drive. This type of base is illustrated in Fig. 13. Note that the tight side is closest to the pivot point. Vertical updrives are taken care of with standard floor mounting by moving the motor as far out on the arms as possible.

The majority of motor-base installations utilize the standard floor mounting. For these, drive tables have been developed which show the proper horizontal distance between the pivot point and the center of the motor shaft, for various angles, motor pulley sizes, and motor frame sizes. This dimension is approximately the same for a given frame size, regardless of horsepower and speed.

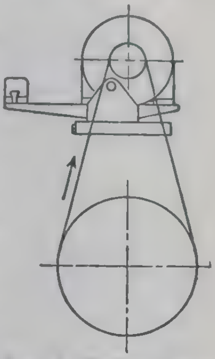

FIG. 13. Vertical downdrive mounting for Econ-O-Matic motor base.

23. SPRING-TENSION MOTOR-BASE DRIVES

The Automatic motor base, manufactured by the Automatic Motor Base Company, Paterson, N. J., is particularly suited for use with smaller motors on belt drives. It consists of a pressed steel base, in which two parallel rails are rigidly mounted, and a plate which can slide or, in the larger sizes, roll along the rails (Fig. 14). The motor is bolted to the plate, and belt tension is applied through springs that are readily adjusted to give the desired tension.

The base can be mounted in any position, and the operation of the base is independent of the direction of rotation of the motor. It can be used with flat leather, flat rubber, or V-rubber belts, which should be selected on the same basis as for a fixed center drive with proper consideration for peak starting load of the motor and other conditions.

The Automatic base is made in twelve sizes to accommodate motors from $^1/_6$ to 100 hp. The NEMA frame number determines the size of the base to be used. Extra-heavy springs can be supplied when the motor is mounted vertically above the driven pulley.

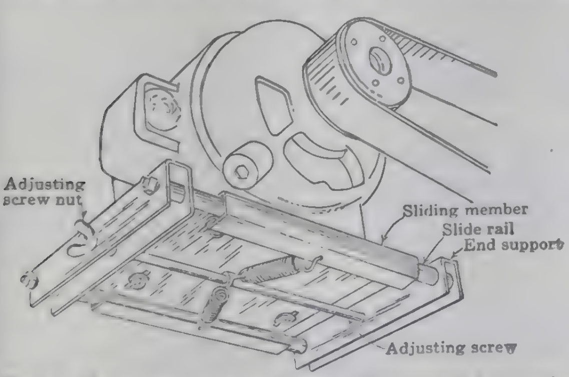

FIG. 14. Spring-tension motor base. (Courtesy of Automatic Motor Base Co.)

The actual installation is a simple operation as illustrated by the following brief instructions:

Turn the adjusting screw until the sliding member is located at the end of the frame nearest the driven pulley. This will permit maximum take-up as belt stretch occurs. Bolt the motor to the sliding member. Position the motor and base assembly so that the belt or belts, in the case of a multiple V drive, go over the pulleys readily. Bolt the assembly in place. Turn the spring adjusting screw until a slight tension is applied to the belt. Start the motor and make the final adjustment, providing only as much spring tension as is necessary for the belt to handle the maximum load without slippage. More tension than is necessary serves no useful purpose and merely puts an undue stress on belts and bearings.

CHAIN DRIVES *

Precision steel roller chains and inverted tooth or silent chains are classified as power transmission chains. Block chains and malleable chains are sometimes used for power transmission purposes at very slow speeds or at very light loads. However, their major use is in the field of conveyor applications. For the transmission of power at average to high speed conditions, it is essential that roller or inverted tooth chains be used.

24. ROLLER CHAINS

Roller chain is a series of alternately assembled roller links and pin links in which the pins articulate inside the bushings and the rollers are free to turn on the bushings. Pins and bushings are press fit in their respective side plates. The chain may be single strand having one row of roller links, or multiple strand having more than one row of roller links and having center plates located between the strands of roller links.

Precision steel transmission roller chains have been standardized by the Association of Roller and Silent Chain Manufacturers and conform to the American Standard B29a-1930 (now being revised and restandardized). The following material has been supplied by the Association, and most of it is as proposed for revision of these ASA standards.

GENERAL CHAIN PROPORTIONS AND DESIGNATIONS.

Roller diameter is approximately five-eighths of the pitch.

Chain width is defined as the minimum distance between the roller link plates. This width is the nearest binary fraction to five-eighths of the pitch.

Pin diameter is approximately five-sixteenths of the pitch or one-half of the roller diameter.

Thickness of link plates for the standard series is approximately one-eighth of the pitch. Thickness of link plates for the heavy series chain of any pitch is approximately that of the next larger pitch standard series chain.

Maximum width of roller link plates = 0.95 of the pitch.

Maximum width of pin link plates = 0.82 of the pitch.

Minimum ultimate tensile strength of standard series chains = 12,500 × $(\text{pitch})^2$ per strand of chain.

Measuring load is the load under which a chain should be measured for length. It is equal to 125 × $(\text{pitch})^2$, with a minimum of 18 lb.

Standard Chain Numbers. The right-hand digit in the chain designation is zero for roller chains of the usual proportions, 1 for a lightweight chain, and 5 for a rollerless bushing chain. (See Table 1.) The numbers to the left of the right-hand figure denote the number of $^1/_8$ inches in the pitch. The letter H following the chain number denotes the heavy series. The hyphenated number 2 suffixed to the chain number denotes a double strand, 3 a triple strand, 4 a quadruple strand chain, and so forth.

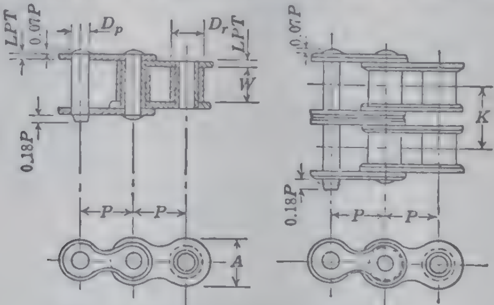

FIG. 1. Chain assembly and nomenclature.

P = chain pitch.
D_r = roller diameter.
LPT = link plate thickness.
A = link plate width.
W = chain width between roller link plates.
D_p = pin diameter between pin link plates.
K = transverse pitch for multiple chains.

Heavy series chains made in $^3/_4$-in. and larger pitches differ from the standard series in thickness of link plates. Their value is only in the acceptance of higher tensile or jerk loads during operation at lower speeds.

Lightweight machinery chain, designated as No. 41, is 1/2 in. in pitch and 1/4 in. wide. It has 0.306-in. diameter rollers, 0.141-in. pin diameter, and 0.050-in.-thick link plates. The measuring load is 18 lb.

Tolerance for Chain Length. New chains, under standard measuring load, may be over-length 1/64 in. per ft but must not be under-length.

Standard offset links are made to accommodate chains having roller link plates with a maximum width, after being beveled, equal to 95% of the pitch, and pin link plates with a maximum width, after being beveled, equal to 82% of the pitch. Therefore the standard minimum values of x and y (Fig. 2) are:

$$x\ (\text{min}) = 0.41P + 0.008\ \text{in.}$$
$$y\ (\text{min}) = 0.475P + 0.008\ \text{in.}$$

where P = chain pitch.

SELECTION OF PRECISION STEEL ROLLER CHAINS FOR POWER TRANSMISSION PURPOSES. For each pitch of chain there is a maximum sprocket revolutions per minute which should not be exceeded without consulting the chain manufacturer. Because of this, it is well to begin the selection of the drive with consideration of the fastest rotating shaft of the drive. Next, refer to Table 2, and select the maximum pitch chain which will operate at the speed of the fastest turning shaft. In the selection it is always advisable to have at least 17 teeth in the smaller sprocket and preferably 24. A smaller pitch chain than selected may be found necessary if the number of teeth is too few or if extreme quietness is desired.

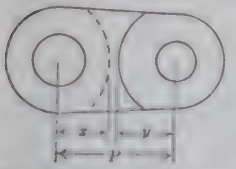

Fig. 2. Offset link plate.

After selection of the chain pitch and number of teeth in the smallest sprocket, check the sprocket for accommodation of the shaft and keyway. The bore should not exceed approximately seven-tenths of the maximum hub diameter (see Fig. 3).

The life of a roller chain drive can be affected adversely by any one of the following causes: (1) small sprockets operating at high speeds, (2) insufficient and improper lubrication; (3) inaccurate sprockets; (4) misalignment of sprockets; (5) overtensioning of chain during adjustment of centers or adjustment of idler sprocket.

The number of strands of chain required are determined from service factors and horsepower ratings, as explained in the following.

HORSEPOWER RATINGS OF AMERICAN STANDARD SINGLE-STRAND ROLLER CHAIN, condensed in Tables 3 to 13, have been established on a life expectancy of approximately 15,000 hr under optimum drive conditions and a service factor of 1. Principles and service factors subsequently outlined must be adhered to in making selections from the rating tables. Failure to do so may result in unsatisfactory service from abnormal joint wear, accelerated chain elongation, and serious damage to sprockets.

The horsepower ratings are for drives with two sprockets. For design of installation having more than two sprockets, idlers, and unusual conditions or requirements, engineers of chain manufacturers should be consulted.

Lubrication		Type I				Type II				Type III	

SERVICE FACTORS as given in the following tabulation should be used in connection with the horsepower ratings, the load being multiplied by the factor to obtain the required chain capacity:

Type of Load	Conditions of Service 10-hr Day	Conditions of Service 24-hr Day
Uniform load, average conditions	1.0	1.2
Moderate shock, abnormal conditions	1.2	1.4
Heavy shock, abnormal conditions	1.4	1.7

LUBRICATION of roller chains is essential for effectively minimizing metal-to-metal contact of pin-bushing joints of the chain. Oil should be applied to link plate edges as explained under Type I method of lubrication subsequently, since access to pin-bushing clearances is possible only through clearances between pin link plates and roller link plates of single chains, and, in addition, between center link plates and roller link plates of multiple chains. Oil applied on center line of rollers cannot reach pin-bushing joints and therefore cannot retard chain wear elongation.

A good grade of mineral oil, without additives, of medium or light consistency, free flowing at the prevailing temperature, should be used.

Drives should be protected against dirt and moisture. The method of lubrication, which is influenced by the speed of the chain and the amount of power transmitted, should be in accordance with one of the following:

Type I. Drip (4 to 10 drops per minute), shallow bath, or manual with oil applied frequently with a brush or spout can to upper edges of all link plates in the lower span of chain.

Type II. Rapid drip (20 drops per minute minimum) or continuous with shallow bath, disk, or slinger. A circulating pump may be required when transmitted horsepower is substantial and center distance is short.

Type III. Continuous, with disk, slinger, or circulating pump.

The choice of method or type of lubrication should in general be guided by the following:

Chain Speed	Method of Lubrication
Up to 600 ft per min	Type I
600 to 1500 ft per min	Type II
Above 1500 ft per min	Type III

Heavy oils and greases are not recommended for lubrication of roller chains except under unusual conditions of service because they are generally too stiff to enter and fill the small clearances between the chain parts. Engineers of chain manufacturers should be consulted in regard to lubrication of roller chain drives for which lubrication other than as outlined might seem to be desirable.

SPROCKETS should have tooth shape, thickness, profile, and diameters conforming to the standards. Smaller sprockets, 25 teeth and less, are preferably of steel, 180 Brinell minimum for speeds to about 600 ft per min. For speeds greater than 600 ft per min, either .20 carbon steel, carburized, hardened and drawn, or .40 or higher carbon steel, heat treated and drawn, are generally recommended, the hardness usually being between 300 Brinell minimum and 550 Brinell maximum depending upon the type of service.

Larger sprockets may be made from unhardened steel plates, bars, castings, or forgings, or cast iron, depending on the duty imposed.

Sprocket dimensions are illustrated in Fig. 3. Using the notation P = pitch, inches; PD = pitch diameter, inches; D_r = roller diameter, inches; and N = number of teeth, the following equations relate the various diameters:

$$\text{Bottom diameter of sprocket} = PD - D_r$$

$$\text{Pitch diameter of sprocket} = \frac{P}{\sin \dfrac{180}{N}}$$

$$\text{Caliper diameter for } \textit{even} \text{ number of teeth} = \text{Bottom diameter}$$

$$\text{Caliper diameter for } \textit{odd} \text{ number of teeth} = PD\left(\cos \frac{90^\circ}{N}\right) - D_r$$

Tolerances on caliper diameter of sprockets:

$$\text{Plus tolerance} = 0.000 \text{ in.}$$

$$\text{Minus tolerance} = 0.001P\sqrt{N} + 0.003 \text{ in.}$$

$$\text{Approximate outside diameter of sprocket} = P\left(0.6 + \cot \frac{180}{N}\right)$$

Maximum hub and groove diameter (MHD) of sprockets

$$= P\left(\cot \frac{180}{N} - 1\right) - 0.030 \text{ in.}$$

Types of Sprockets. The designations for the four principal types of sprockets are as follows (see Fig. 4):

- Type A—plain plate
- Type B—hub on one side only
- Type C—hub on both sides
- Type D—hub detachable

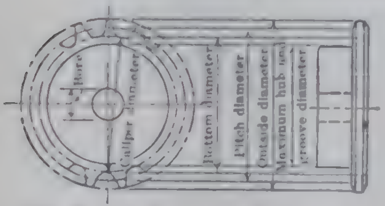

FIG. 3. Chain sprocket dimensions.

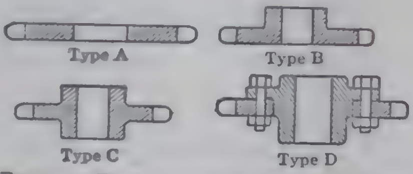

FIG. 4. Four principal types of chain sprockets.

The section profile (Fig. 5) shows the recommended chamfering of sprocket teeth for roller chains and tooth flange location for multiple strand chains. Dimensions are given in Tables 14 and 15. Other dimensions are given by the following relationships: P = pitch of chain; w = chain width; LPT = nominal thickness of link plates; $k = W + (4.22$

$\times$ LPT) = transverse pitch for multiple strand chains; M_2, M_3, M_4, etc. = k (strand multiple $-$ 1) + t; R_c min = $1.063P$ (approximately tangent to side) = chamfer radius; and r_f max = $0.04P$ for maximum hub diameter = fillet radius.

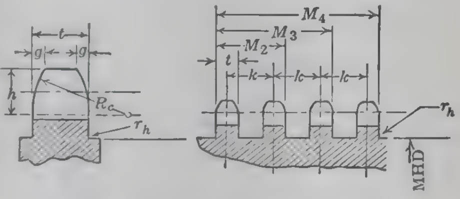

FIG. 5. Profile of sprocket teeth.

Cutters for Sprocket Teeth. Three types of cutters are used for cutting sprocket teeth, viz., space cutters, straddle cutters, and hobs. Space cutters will cut the following ranges of teeth: 7 to 8, 9 to 11, 12 to 17, 18 to 34, 35 and over. These cutters are of the common type, designed to cut the spaces between the teeth. Straddle cutters are designed to straddle the teeth and cut a part of two spaces at the same time. Two straddle cutters will fill the requirements for all numbers of teeth. Hobs are made to cut any required number of teeth of a given pitch and roller diameter. Proportions of cutters are given in American Standard B29a-1930 (now in process of revision) or may be secured from roller chain manufacturers.

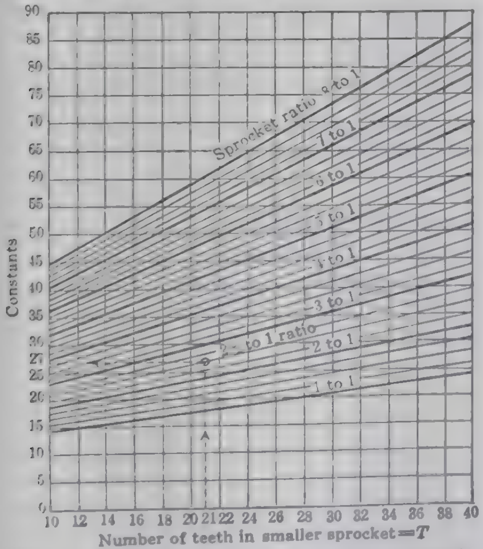

FIG. 6. Desirable chain centers. The constants multiplied by pitch give approximate center distance in inches. (Courtesy of Link-Belt Co.)

ALIGNMENT of shafting and sprocket tooth faces must provide distribution of the load across the entire chain width. Shaftings, bearings, and foundations should be suitable to maintain the initial static alignment. The horsepower tables are directly applicable only if the sprockets are on parallel, horizontal shafts.

CENTER DISTANCE between sprockets should be sufficient to provide approximately 135 degrees minimum arc of meshing of the chain on the smaller sprocket. Approximate centers may be obtained from Fig. 6. For low powers and speeds the distances given by Fig. 6 can be reduced to a point where the sprockets just clear on low ratios, and where arc of contact is no less than about 100 degrees on small sprockets with large ratios. Centers and sprockets selected should allow adequate clearance for slack strand of drive. Means for adjustment of center distance is recommended especially if there is fluctuation of load or if the sprockets are on vertical centers. Centers should be selected for chain length of an even number of pitches.

LENGTH OF CHAIN for two-sprocket drives is given exactly by the following formula:

$$L = \frac{N + n}{2} + \phi \frac{N - n}{180} + 2C \cos \phi \qquad (1)$$

where N and n are, respectively, the numbers of teeth in the large and small sprockets, C = center distance, and $\phi = \sin^{-1}[(N - n)/2\pi C]$ measured in degrees. Lengths L and C are measured in terms of pitches. For most purposes, the following approximation will serve:

$$L = \frac{N + n}{2} + \frac{(N - n)^2}{4\pi^2 C} + 2C \qquad (2)$$

Although chain lengths may be calculated by the foregoing formulas, it is recommended that a careful layout be made to scale, full size, or double size, from which length may be measured by stepping off with dividers. Such layouts may be studied so that proper ratios, adjustment, etc., can be provided and should be submitted to the chain manufacturer for checking and approval. For drives employing more than two sprockets, the layout method is the fastest for determining chain length.

25. SILENT CHAINS

A silent or inverted-tooth chain consists of a series of links of the shape shown in Fig. 7, which are assembled over pins to form various widths of chain, as shown in Fig. 8. The chain engages with the sprocket as shown in Fig. 9. As the pitch lengthens, owing to wear, the links adjust themselves to a larger pitch circle as shown in Fig. 10, thus automatically compensating for wear. These chains can be run in either direction at velocities up to 4,500 ft per min, quietly and smoothly, on sprockets of suitable numbers of teeth.

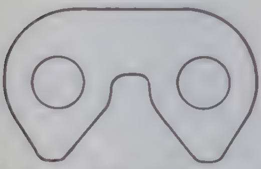

FIG. 7. Elementary link of silent chain.

FIG. 8. Silent chain.

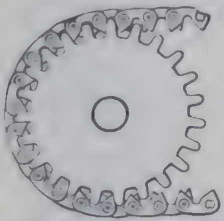

FIG. 9. New chain on sprocket.

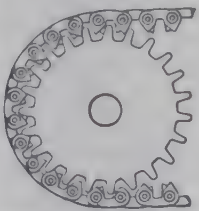

FIG. 10. Worn chain on sprocket.

DESIGN OF CHAIN DRIVES. Design must always be based on nature of load, horsepower (hp) to be transmitted, and revolutions per minute (rpm) of driving and driven units.

Before the design is selected, the nominal or given horsepower should be multiplied by a service factor in accordance with Table 16, which is based on the necessary extra capacity required for severity of conditions.

Table 16. Service Factors *K* for Silent Chains

	10-hour Day or Less		24-hour Day	
Nature of Load	Motor or Turbine Drive	Internal-Combustion Engine Drive	Motor or Turbine Drive	Internal-Combustion Engine Drive
Uniform	1	1.3	1.3	1.7
Moderate shock	1.3	1.7	1.7	2
Heavy shock	1.7	2	2	2.5

Pitch of chain should be selected first on the basis of values given in Table 17. The higher shaft speed is the limiting factor and indicates the largest pitch chain that can be used. Also, the diameter of this shaft must be checked with the largest recommended bore that can be used in the sprocket selected. In general, the largest pitch gives the best drive, but limitations of sprocket diameters and necessity for quiet operation often dictate smaller pitches. For the quietest drive, the smallest pitch that will carry the load should be chosen. Large pitch chain should be used for slow speeds and larger power.

Table 17. Silent Chain Drive Data

Pitch, in.	Pitches per Foot	Chain Widths, in.	Approx. Weight per Foot, 1-in. Wide, lb	Small Sprocket Driver: Normal Revolutions per Minute	Small Sprocket Driver: Maximum Revolutions per Minute *	Small Sprocket Driver: Recommended Minimum No. of Teeth on Driver †
3/8	32	3/8–4	0.75	4000	6000	19
1/2	24	1/2–7	1.00	2600	4000	19
5/8	19.2	1–8	1.25	2300	3500	19
3/4	16	1–10	1.50	1650	2500	21
1	12	1 1/2–14	2.00	1300	2000	21
1 1/4	9.6	2 1/2–20	2.50	1000	1500	23
1 1/2	8	3–24	3.00	800	1200	23
2	6	4–30	4.00	600	900	25

* Under favorable conditions these values may be exceeded, and under unfavorable conditions they must be decreased.

† Smaller numbers of teeth on the driver may be used under certain conditions. For these drives, consult manufacturer.

Speed ratio is the basis of selection of driving and driven sprockets. The smaller sprocket is usually selected first on the following basis:

Speed Ratio	1 : 1	2 : 1	3 : 1	4 : 1	5 : 1
Number of Teeth of Small Sprocket	25–35	19–29	19–25	19–23	19–21

Ratios as high as 8 to 1 are possible, but the use of sprockets of less than 17 teeth or more than 120 teeth are to be avoided in the interests of long life and efficient operation. See Table 18, listing desirable sprocket combinations and giving various ratios.

Table 18. Ratio Table

Ratio	Pinion	Sprocket	Ratio	Pinion	Sprocket
1.00	25	25	2.71	21	57
1.09	23	25	3.00	19	57
1.10	21	23	3.04	25	76
1.11	19	21	3.3	23	76
1.19	21	25	3.62	21	76
1.21	19	23	3.80	25	95
1.32	19	25	4.00	19	76
1.52	25	38	4.13	23	95
1.65	23	38	4.52	21	95
1.81	21	38	4.56	25	114
2.00	19	38	4.95	23	114
2.28	25	57	5.00	19	95
2.48	23	57	5.43	21	114

Chain speed is determined by the equation

$$\text{Chain speed (fpm)} = \frac{\text{Number of teeth} \times \text{rpm} \times \text{pitch (in.)}}{12}$$

Chain width is determined on the basis of values of horsepower per inch of width of chain, given in Table 19. Then

$$\text{Chain width} = \frac{\text{Horsepower} \times K}{\text{Horsepower per inch of width}}$$

where K is the service factor, Table 16. Available chain widths may be obtained from the manufacturers' catalogs.

It is usually possible to arrive at two or more different sound design selections for the same set of data. Try to select a pitch and sprocket size that will allow a chain width of less than eight times the pitch. Manufacturers of silent chain should be consulted concerning drives involving unusual conditions.

Chain length is determined by either of the equations 1 or 2, page 15-76. Arrange centers for an even number of pitches where possible, thus avoiding the use of offset links in the chain.

Center Distance. Minimum center-to-center distance between sprockets is the sum of the sprocket diameters for drives, under normal conditions. Long centers are practical on drives where provision is made for adjustment for chain wear or "stretch."

SILENT CHAIN SPROCKETS.

$$\text{Pitch diameter} = \frac{\text{Pitch}}{\sin \dfrac{180°}{N}}$$

Outside diameter is approximately that of the pitch diameter. To determine the approximate diameter of the chain when wrapped around the sprocket, add 1.25 times chain pitch to pitch diameter.

Approximate weight in pounds of steel pinions = $T^2 \times (F + 1) \times c$

where T = number of teeth, F = face in inches, and c = pitch constant given below.

Pitch	3/8	1/2	5/8	3/4	1	1 1/4	1 1/2	2
	.003	.0045	.0063	.009	.016	.025	.035	.028

Approximate weight in pounds of spoke-type sprockets = $T \times F \times C$

where T = number of teeth, F = face in inches, and C = pitch constant given below.

Pitch	3/8	1/2	5/8	3/4	1	1 1/4	1 1/2	2
C	0.10	0.16	0.25	0.35	0.60	0.75	1.00	2.00

For approximate weight of *split* sprockets, add 25%.

PROTECTION AND LUBRICATION. Silent chain drives, wherever possible, should be operated in an oiltight casing with provision for lubrication.

When the chain speed is less than 1500 ft per min, a drip or sight-feed oiler may be used. The oil should be applied to the inner surface of the chain at the rate of about one drop per minute per inch of width.

When the chain speed is from 1500 to 3000 ft per min, bath lubrication is recommended. The oil is maintained at a level in the lower portion of the casing so that the chain, while running, will be immersed to a depth of approximately one-half the pitch.

The viscosity of the oil depends somewhat upon temperature conditions and the chain speed but in general should be a straight mineral oil of a viscosity of about SAE 30. Heavy-bodied oil such as SAE 50 or 60 may be used on very slow-moving chains. Greases of any kind should be avoided as they cannot at ordinary temperatures penetrate to the "joint" of the chain where lubrication is most needed.

ROPE DRIVING

Since electrical transmission of energy has largely displaced rope driving as a power transmission medium, only a brief discussion of rope drives is included here. More detailed information may be obtained from the eleventh edition of Kent's *Mechanical Engineer's Handbook, Design and Shop Practice* volume.

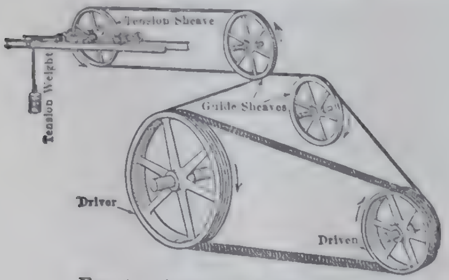

FIG. 1. Continuous rope drive.

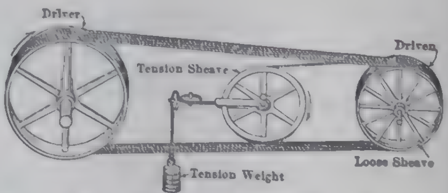

FIG. 2. Continuous rope drive with loose sheave.

26. MANILA AND COTTON ROPE DRIVES

SYSTEMS OF ROPE DRIVING. Two systems of rope driving are in use: (1) the American or continuous system (Figs. 1 and 2) in which a single rope passes over the sheaves several times, the slack being taken up by a tension carriage, which also transfers the rope from the outside groove of the driven sheave to the opposite outside groove of the driving sheave; (2) the English multiple system, comprising one or more separate ropes alongside of each other in the pulley sheaves.

The continuous system is adapted to drives where the shafts are not parallel, to vertical drives, and to drives where the rope is exposed to the weather. A disadvantage, however, is that the breakage of a single strand puts the entire drive out of service.

The arrangement of the tension carriage is important. The slack preferably should be taken up on the slack side of the drive at the driving sheave. (See Fig. 1.) If this is not possible, it may be taken up at the driven sheave. (See Fig. 2.) The outside groove of the driven sheave then should be a loose sheave, and the rope led to it from the tension sheave, whence it is returned to the opposite outside groove on the driving sheave. The weight applied to the tension carriage should be just sufficient to prevent any tendency for the rope to slip. It can be approximated from the value of the tension in the slack side, as calculated by formula 4.

The English multiple system, using separate parallel ropes, has no tension carriage but depends on the weight of the ropes to provide the necessary tension. The power transmitted by a given drive may be increased at any time by the installation of additional ropes. An advantage of this system is that the breakage of a single rope does not put the drive out of service. Disadvantages are the difficulty of maintaining uniform tension on the several ropes, with resultant excessive wear on the more heavily loaded ones; the necessity of protecting the drive from the weather; the inability to use it for vertical drives; and the requirement that the distance between sheaves must be sufficiently long to give the necessary tension on the ropes.

HORSEPOWER OF ROPE DRIVES. Let T = working tension in rope, pounds; T_1 and T_2 = the total tension in tight and slack sides of rope, respectively; t_1 and t_2 = effective tension in tight and slack sides of rope, respectively, pounds; t_c = tension due to centrifugal force; V and v = velocity of rope, feet per minute and feet per second, respectively; w = weight of rope per foot, pounds; d = diameter of rope, inches; S = breaking strength of rope, pounds. Then

$$T = (t_1 - t_2) \tag{1}$$

$$t_c = \frac{wv^2}{g} = \frac{wv^2}{32.2} \tag{2}$$

$$\text{Horsepower} = \frac{TV}{33{,}000} \tag{3}$$

Tension t_1 may be considered as made up of (1) tension doing useful work, (2) tension to balance the tension necessary for adhesion, and (3) tension due to centrifugal force. Tension t_2 may be considered as made up of (1) tension necessary for adhesion T_a and (2) tension due to centrifugal force t_c.

Tension on the tight side is assumed to be double that on the slack side. Then $T_a/T = 1/2$, and $T_a = 1/2\ T$. Since $T_a = t_2 - t_c$, $t_2 = t_c + 1/2\ T$, and

$$T = t_1 - t_c - 1/2\ T \tag{4}$$

from which

$$T = 2/3\,(t_1 - t_c) \tag{5}$$

Substituting the value of T from 5 in eq. 3,

$$\text{Horsepower} = \frac{2/3\,(t_1 - t_c)V}{33{,}000} \tag{6}$$

According to the American Manufacturing Co., t_1 should be limited to $1/35\ S$, and S may be taken as $7000d^2$, whence $t_1 = 200d^2$. Substituting the values $t_1 = 200d^2$ and $t_c = wv^2/32.2$ in eq. 6, we have

$$\text{Horsepower} = \frac{2/3\ V\left(200d^2 - \dfrac{wv^2}{32.2}\right)}{33{,}000}$$

$$= 0.0000222\ V\left(200\ d^2 - \frac{wv^2}{32.2}\right) \tag{7}$$

For theoretical discussion of the effect of arc of contact and coefficient of friction on the transmission of power by belts, bands, ropes, etc., see Article 16 in this section.

Since the value of T_c increases with the velocity of the rope, it is obvious that there is a certain speed at which the maximum horsepower will be transmitted. For a tension in the tight side of 200 psi, this is in the neighborhood of 80 ft per sec as shown by Fig. 3.

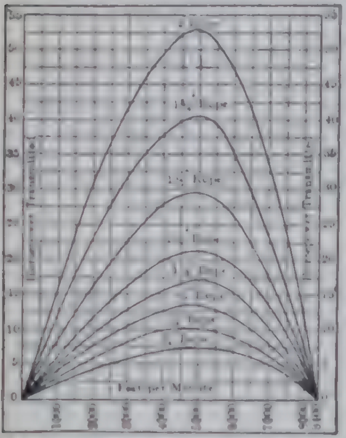

FIG. 3. Horsepower transmitted by manila rope.

Sag of Rope. The catenary of the driving side is not affected by the speed or by the diameter of the rope. The deflection of the rope between the pulleys on the slack side varies with each change of load or speed. The deflections D and D_1, or sag in the tight and slack sides, respectively, for horizontal drives may be approximated from eqs. 8 and 9, t_1 being taken as $200d^2$, and L being distance between sheaves, feet.

$$D = \frac{wL^2}{8t_1} \tag{8}$$

$$D_1 = \frac{wL^2}{8t_2} \tag{9}$$

The value of t_2 is found from eqs. 4 and 5. Equations 8 and 9 will closely approximate the sag on the driving side for both multiple and continuous systems, and also the sag on the slack side in the continuous system. In the multiple system the equation for the slack side is true only when the ropes are first spliced on the pulleys, as the stretch in new ropes, when they are put in motion, rapidly increases the sag.

SHEAVES. The larger the sheaves, the less the internal wear of the rope. Sheaves should not be less than forty times the diameter of the rope for economical wear, and as much larger as it is possible to make them. This rule applies also to idler and tension sheaves.

Figure 4 shows the form of the grooves in driving and driven sheaves, for the continuous system. The grooves for the multiple-rope system are of similar form, but deeper, and the angle of the grooves is 30 degrees, instead of 45 degrees. Figure 5 shows the form of grooves recommended for carrier and idler sheaves in the continuous-rope system. Grooves should be well polished to avoid wear on the ropes. They also should be free from sand- or blowholes, which tend to cut the rope rapidly.

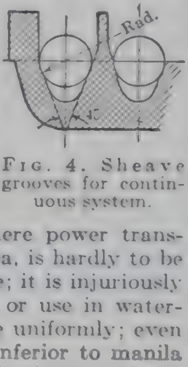

FIG. 4. Sheave grooves for continuous system.

ROPE MATERIALS. Cotton ropes are largely used in Great Britain but only to a limited extent in the United States where the preference is for manila rope. The American Manufacturing Co. states that cotton ropes are advantageously used as bands or cords on the smaller machine appliances. The fiber, being softer and more flexible than manila hemp, gives good results for small sheaves; but for large drives, where power transmitted is in considerable amounts, cotton rope, as compared with manila, is hardly to be considered, on account of the following disadvantages: It is less durable; it is injuriously affected by the weather, so that for exposed drives, paper-mill work, or use in water-wheel pits, it is unsatisfactory; it is difficult, if not impossible, to splice uniformly; even the best quality cotton rope is much inferior to manila in strength—the breaking strain of the highest grade being but 4000 × diameter^2 as against 7000 × diameter^2 for manila, whereas, for the transmission of equal powers, the cost of a cotton rope varies from one-third to one-half more than manila. See also Article 5, Section 6.

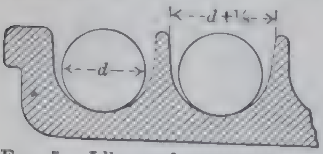

FIG. 5. Idler and carrier sheave grooves.

SHEAVE CENTER DISTANCES. The distance between the axes of the sheaves of rope drives, where the tight strands are on the bottom, depends on the sheave diameters. The slack strands should clear the tight lower strands by at least $0.1L$, where L = center-to-center distance of the sheaves. Where the tight strand is on top, L may be as great as 100 ft, provided that shafts and bearings are sufficiently rugged to withstand the strain of the extra weight of rope. It is not advisable to make the distance between the faces of the sheaves less than 25 ft.

27. WIRE ROPE TRANSMISSION

For data on the various types of wire rope available for power transmission, including construction and breaking strength, see pp. 6-09 to 6-20.

WIRE ROPE SHEAVES. Sheaves used with wire rope for the transmission of power are of the form shown in Fig. 6. The bottom of the sheave is filled with blocks of rubber or leather. The minimum diameter of sheave that should be used with 6 × 7 wire rope is $100d$, where d = diameter of rope. With 6 × 19 rope, the minimum sheave diameter should be $66d$. Sheaves must be set true on the shafts and at right angles to the line of transmission to avoid wear on the rope and loss of power. Guide sheaves and supporting sheaves should not be used unless absolutely necessary, for the same reasons. In designing wire rope transmissions to transmit a given horsepower, a choice frequently can be made between small sheaves running at high speed and large sheaves running at a lower speed. Since the wear on the rope always is greater in bending over small sheaves, economy in life of rope will be served by selecting the larger sheaves and lower speeds.

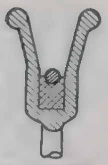

FIG. 6. Wire rope sheave groove.

FRICTION GEARING

FRICTION GEARING. If two cylinders with parallel axes are in contact and one of them rotates upon its axis, the friction between the surfaces will drive the other cylinder. The driving capacity depends upon the coefficient of friction of the material of the wheels, the pressure with which they are held in contact, and the length of the cylinders. In order to secure good frictional conditions, one member only of a friction gearing is of metal; the other is of a composition giving a high coefficient of friction with metal. The composition wheel is always the driving member, and its slip on the driven tends to distribute the wear uniformly over its surface. Friction gearing cannot be used if positive driving is essential, as it is always liable to slip. It may be used where the power to be transmitted is not very great; where the speed is so high that toothed wheels would be noisy; where the shafts are frequently to be put in and out of gear or to have their relative directions of motion reversed; or where the velocity ratio is to be changed while the machinery is in motion.

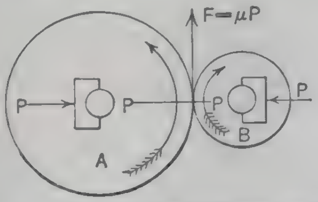

FIG. 1. Forces in plain friction gearing.

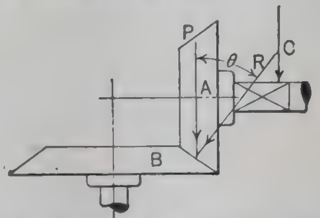

FIG. 2. Forces in bevel friction gearing.

POWER TRANSMITTED BY FRICTION WHEELS. The tangential force that can be transmitted by two friction gears is equal to the product of the total normal pressure and the coefficient of friction. Thus, in Fig. 1 let P = total normal pressure, pounds, and μ = the coefficient of friction; then the resultant tangential force $F = \mu P$. If V = velocity of the surface of the friction wheels, feet per minute, the horsepower transmitted = $\mu PV/33000$. If d = diameter of the driver, inches; l = length of the face, inches; w = allowable load per inch of face, pounds; N = revolutions per minute,

$$\text{Horsepower} = \frac{\mu wl \times 3.1416dN}{12 \times 33000} = 0.000008\mu wldN$$

In *bevel wheels*, Fig. 2, the resultant R of the applied force P presses the wheels together, and $R = P \div \cos\theta$. The velocity of the mean circumference of the driver may be taken as the velocity of transmission.

Table 1. Pressure and Friction Coefficient of Friction Gear Materials

Material	w	μ with Cast Iron	Material	w	μ with Cast Iron	μ with Aluminum
Cast iron	3000	.15	Straw fiber	150	.15	.16
Cork composition	50	.21	Leather fiber	240	.18	.18
Paper	150	.15	Tarred fiber	240	.09	.11
Rubber	100	.20	Sulfite fiber	140	.20	.19
Wood	150	.15	Leather	150	.08	.13

Table 1 gives allowable load per inch of face, w, for various materials, the values being approximately one-fifth of the load which would cause failure. The friction coefficients shown in the same table are approximately 60% of the maximum and represent safe design values with allowance for deterioration in service, decrease in normal pressure, etc.

WEDGE-FACED OR GROOVED FRICTION WHEELS give greater resistance to slipping with a given radial pressure. In Fig. 3, P = the radial force applied to the grooved surfaces, pounds; F = the tangential force transmitted, pounds; $R/2$ = the reaction on each face; and 2θ = the angle of the groove. The wedge is held in equilibrium by the force P, the reactions $R/2$, and the frictional resistance $\mu R/2$ due to the wedging action. Then $R = F/\mu$; $P = R \sin \theta + \mu R \cos \theta$; $F = \mu P/(\sin \theta + \mu \cos \theta)$. As before, the tangential force that can be transmitted by the gears is the product of the total normal pressure and the coefficient of friction. The number of wedges has no influence on the power transmitted but decreases the wear by distributing it over several surfaces.

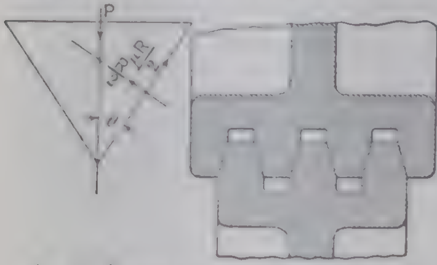

Fig. 3. Forces in grooved friction wheels.

The angle 2θ of the grooves varies from 30 to 40 degrees, but to avoid sticking it should never be less than 30 degrees.

VARIABLE-SPEED DRIVES

By E. L. Schwarz-Kast

Every machine has an optimum speed at which operation is most efficient or production maximum. With the same machine this optimum speed may differ for various circumstances or products over a wide range and can seldom be accurately predetermined. Frequently, speed changes are necessary during operation. Often a run with creeping speed prior to the actual operation is required for adjustments, or for positioning of tools and workpieces. These requirements were recognized in the early days of primitive machines, and much effort has been directed toward finding convenient methods of speed control. Step pulleys, cone pulleys, friction disks, variable pitch pulleys, and shifting gears were steps in this development.

The following check list is recommended as an aid in selection of the most appropriate system for a particular drive:

CHECK LIST

1. Necessary speed range.
2. Are several definite speed steps or continuous speed variations needed?
3. Speed regulation at any adjusted speed step:

$$\text{Speed regulation (\%)} = \frac{(\text{No load speed} - \text{full load speed})}{\text{Full load speed}} \times 100$$

Sometimes a constant speed or a very small regulation is required. At other times a falling speed characteristic is desirable so that overload will cause a drop in speed, thus protecting motor and gears against peak loads.

4. Torque-speed characteristics of the load should be known. The following three groups of loads are quite common: (*a*) torque constant over the entire speed range, the horsepower varying proportionally with the speed (for example, pure friction load or reciprocating compressors); (*b*) horsepower required constant, the torque varying inversely as the speed (e.g., some machine tools); (*c*) variable torque (e.g., fans, propellers, centrifugal pumps, where the torque varies as the square and the horsepower as the cube of the speed).

Torque and horsepower requirements of the load should be known over the entire speed range. Selection must be based on the maximum torque and the speed at which this torque is required. Furthermore, the variable-speed device must also start the load and has to carry at start the actual load torque and, in addition, the necessary torque required to accelerate the load. The following formula is convenient for calculation of the accelerating torque:

$$T = \frac{WR^2 \times \text{revolutions per minute}}{308 \times t}$$

where T = accelerating torque, pound-feet; WR^2 = total moment of inertia of the load, pound-feet^2, reduced to the power input shaft; and t = total time, seconds, for acceleration of the load from zero to full speed.

This check on starting torque is especially important for start of heavy inertia loads.

5. Overall efficiency, power losses, eventual heat dissipation.
6. Continuous or intermittent duty cycle.
7. Simplicity and reliability of operation and speed adjustment.
8. Life. As a rule the lifetime should not be less than that of the machine to be driven.
9. Space requirement.
10. Weight.
11. Speed of response and inertia of the device.
12. Cost.

For good planning a check against a list of this kind is recommended, simply to be sure that nothing of importance is overlooked. In some instances only a few of the items apply, and the others may be unimportant.

Variable-speed devices are divided into three groups: mechanical, hydraulic, and electrical. A brief description of some typical devices in each group is given in the following articles.

28. MECHANICAL VARIABLE-SPEED DRIVES

THE P.I.V. GEAR is a variable-speed device using a chain drive to transmit power from the input to the output shaft. It uses a unique self-tooth-forming chain that runs on the grooved faces of opposing conical surfaced wheels, as shown in Fig. 1. The handwheel moves the control levers in and out of pivots. This movement alters the effective diameters of the opposing wheels and establishes a positive no-slip transmission that gives continuously variable speed. The entire gear is fully inclosed, and all moving parts operate in oil. The only external parts are the speed selection indicator and the control handwheel.

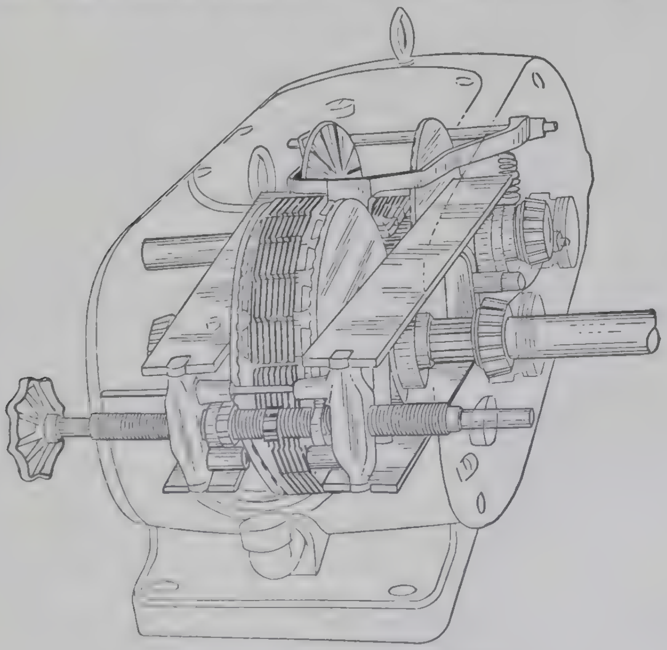

FIG. 1. P.I.V. speed changer. See Table 1.

Table 1 shows the speed ratios, horsepower, and torque ratings of the various sizes, which are available in both horizontal and vertical units. Other standard assemblies include motorized and geared units for output reduction or step-up gearing, and also a bare unit to be built into a machine housing.

The P.I.V. gear is built by the Link Belt Co., Chicago, Ill.

Table 1. Speed and Horsepower Ratings of P.I.V. Gears

VARIABLE-PITCH PULLEYS. The Reeves variable-speed transmission (Fig. 2) consists of two pairs of cone-shaped disks mounted on spline shafts. The disks are carried in bearings on the levers *V*, pivoted at *P*. The handwheel actuates the right- and left-hand screws, causing the levers to rotate about *P*, and thus causing the disks of one pair to approach and those of the other pair to recede from each other as desired. One shaft is connected to the input shaft; the other is connected to the driven shaft. A rubber belt with blocks of hard wood bolted to each face of the belt connects the two pairs of disks. The ends of these blocks are finished at the same angle as that of the disks. The driving force is transmitted by friction between the blocks and the disk faces. When the disks of one pair are widely separated, the diameter of the circle of contact with the blocks is small; it is correspondingly larger on the other pair. By varying the distance between the disks, any desired speed ratio between the driving and the driven shaft can be obtained, within the range of the transmission.

These transmissions (Reeves Pulley Co., Columbus, Ind.) are available in both horizontal and vertical types and both open and enclosed. Capacities range up to 100 hp. Table 2 lists data for selection of the proper size for a given set of conditions. As may be seen from the table, the horsepower rating varies with the speed of the driven shaft. Consequently, for constant-horsepower drives requiring full horsepower at the lowest speed, selection of proper size has to be based on the horsepower requirement at the lowest speed.

The Reeves Vari-Speed pulley (Fig. 3) consists of an assembly of two, facing cone-shaped disks, one stationary, the other sliding laterally, and a compression spring. The whole assembly is mounted on any standard motor shaft. A motor base has an adjusting handwheel by which the motor and disk assembly can be moved forward or backward, and a Reeves V-belt transmits the power to the driven machine. When the motor is nearest to the driven pulley, the V-belt is at largest contact arc over the disks and maximum speed is developed. Turning the handwheel moves the motor away from the driven pulley, the V-belt runs over a smaller arc of contact, and the output speed is reduced. Capacities range from $^1/_8$ to 15 hp at 1800 rpm motor speed, with speed ratios up to 4 : 1.

The Vari-Speed Jr., with capacities up to 1 $^1/_2$ hp, operates on a similar principle but employs standard A- or B-section V-belts instead of special wide belts.

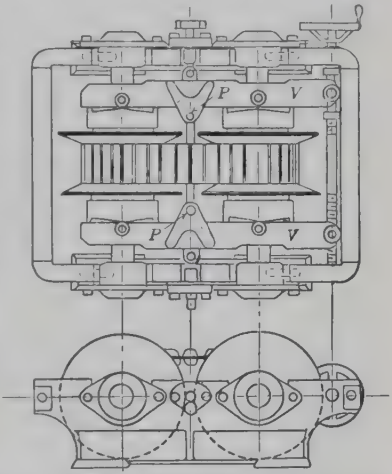

FIG. 2. Reeves variable-speed transmission. See Table 2.

The Vari-Speed motor drive, Fig. 4, combines a standard constant-speed motor, a speed-control mechanism, and, when required, speed-reduction gears. Of the two disks on the motor shaft one is fixed to the shaft, the other being axially adjustable by a handwheel operating through a screw. One of the disks on the variable-speed shaft is fixed to its shaft, the other being axially movable against a spring as shown in Fig. 4. The spring keeps the disk in proper contact with the V-belt, providing correct belt tension. This unit can be furnished in vertical or horizontal types, in capacities from $^1/_4$ to 20 hp, and with speed variation up to 6 : 1 when a single-speed motor is used. A two-speed motor extends the speed range to 12 : 1.

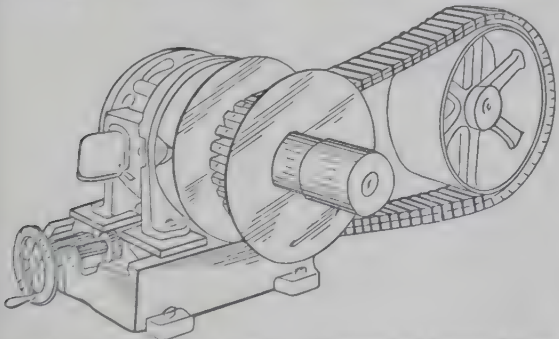

FIG. 3. Variable-speed pulley. (Courtesy of Reeves Pulley Co.)

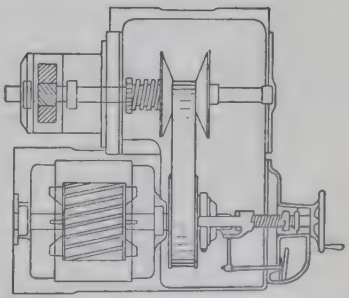

FIG. 4. Combined variable-speed and motor drive. (Courtesy of Reeves Pulley Co.)

Vari-Pitch drive (Allis-Chalmers Mfg. Co., Milwaukee) consists of a Texrope V-belt drive with one or both sheaves arranged so that the grooves can be adjusted to provide a larger or smaller pitch diameter, producing an increase or decrease in speed of the driven shaft. The range of speed variation is from 15 to 20% per sheave at capacities from 1 to 125 hp and larger. For drives requiring greater speed range, wide-range Vari-Pitch sheaves have been developed which provide up to 100% variation at capacities from fractional up to 30 hp.

Vari-Drive (U. S. Electrical Motors, Inc., Chicago, Ill.) is a simple squirrel-cage motor built integral with a variable speed Vari-belt transmission. This transmission consists of a pair of dual disks, and the speed is changed by varying the pitch diameter of the disks.

By turning a handwheel the required disk diameter, the proper distance of the disks and the correct belt tension are simultaneously adjusted. This drive is rated in sizes up to 10 hp and a speed variation up to 7 : 1.

Variable V planetary speed selector (Speed Selector, Inc., Cleveland, Ohio) uses a planetary system, with V-belts and four variable pitch sheaves instead of gears. By the planetary motion combined with the variable-pitch V-belt sheaves, any speed from zero to 800 rpm can be provided at constant torque. Three different sizes are available: 0.5-hp, 1-hp, and 2-hp output at maximum speed of 800 rpm. The speed selector can be installed at any convenient location where a belt from the speed selector to the motor, and another to the driven shaft, can be provided.

Lewellen. The Lewellen Manufacturing Co., Columbus, Ind., has developed variable-pitch pulleys and variable-speed transmissions consisting of one set of pitch-adjustable V-belt disks. The V-belt is a special double block belt. The device is rated in sizes from fractional to 60 hp, vertical or horizontal arrangement, and open or enclosed.

The All-Speed selector (Worthington Pump and Machinery Corp., Harrison, N. J.) uses a combination of two sets of variable-pitch V-belt transmissions. Two sizes, A and C, are available. Model A is rated from $^1/_4$- to $^3/_4$-hp output and has a ratio up to 16 : 1, with a speed range from one-eighth to twice the motor speed. Model C is rated from 1- to 3-hp output and has a ratio up to 9 : 1, with a speed range from two-ninths to twice the motor speed. Provision is made for maintaining the proper belt tension. The belts are Goodyear stretchless steel cable V belts.

Lovejoy. The Lovejoy Flexible Coupling Company, Chicago, Ill., developed variable-pitch V-belt pulleys from fractional up to 8 hp and a maximum speed ratio of 3 : 1. The device consists of a spring-operated variable-pitch pulley, a V-belt, and an adjustable motor base.

Another type is the Select-O-Speed transmission of the same company. Two variable-pitch pulleys are mounted on a common shaft, which runs in ball bearings. The pitch of both pulleys can be changed simultaneously by a common control lever. This device can be inserted in any ordinary V-belt drive and gives a speed ratio up to 10 : 1. It is available in sizes from fractional up to $7\,^1/_2$ hp.

VARIABLE-RATIO ROLLING CONTACT DRIVES. The Graham variable-speed transmission has a range up to 1 hp. Its operation is based on the principle of a ring of fixed diameter in contact with conical rollers, the speed ratio depending on the ratio of the diameter of the ring to the diameter of the rollers at the point of contact. Figure 5 shows a diagram of the drive. Three conical rollers *A* spaced 120 degrees apart are carried in the carrier *B*. The rollers *A* bear with fixed pressure against the contact ring *C* which surrounds the carrier. The position of *C* can be varied axially by means of the control cam *D*; the slot in the cam is spiral in shape to give a linear relation between speed and cam-shaft movement, thus allowing the dial to be calibrated in revolutions per minute, with a uniform scale. The carrier *B* is attached to the drive or input shaft. The rollers *A* carry, at their small ends, pinions *F* which mesh with an internal gear *G*, attached to the driven or output shaft. In operation, as the carrier *B* is rotated, it causes the rollers *A* to revolve around the center line of the carrier. The friction between the rollers and the contact ring *C* causes the rollers to rotate about their own axes and in turn to drive the output shaft through the pinions and gear, *F* and *G*. The rate of rotation of the rollers, and consequently the speed of the output shaft, depends on the position of the contact ring *C*. The speed of the driven shaft is lowest when the ring is in contact with the smallest diameter of the rollers, and highest when it is in contact with the largest diameter. An indicator on the front of the case shows the position of the contact ring and the speed ratio at which the drive is operating.

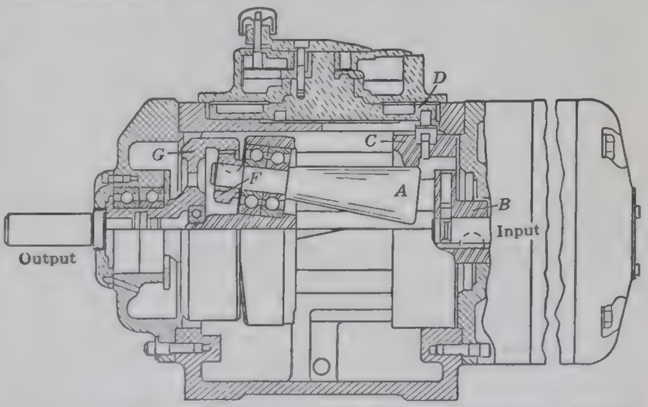

FIG. 5. Variable-ratio rolling contact drive. (Courtesy of Graham Transmissions, Inc.)

Table 3 lists the speed range and the capacity of drives up to 1 hp. In the standard unit, the speed variation is from maximum through zero and slightly into reverse. In the B style (which differs from the standard only in the number of teeth in the pinions and ring gear), equal speeds are had, forward and reverse, without reversing the motor. The drive may be operated by a built-in motor or by a motor coupled to the input shaft It is also made with built-in-spur-geared heads on the output end which reduce the speed of

the output shaft to 1/7, 1/5, or 1/2.8 of the values given by the standard drives and increase the torque accordingly. A similar arrangement may be had with step-up gearing with approximately 2.5 : 1 ratio and corresponding decrease in torque. Worm-geared heads are also available in various ratios, with the output shaft extending horizontally or vertically upward or downward. Table 3 also lists the main overall dimensions. The drive is made by Graham Transmissions, Inc., Milwaukee, Wis.

The Master Speed Ranger (Master Electric Co., Dayton, Ohio) is an all-metal design and consists mainly of a pair of driver cones and a pair of driven cones with a metal ring transmitting the power from the driving cones to the driven cones. Each pair of cones consists of one stationary and one sliding cone. The speed is varied by moving the sliding cones, thus changing the radii of contact with the transmitting ring. The whole unit operates in oil. The units are available from 1/6 to 5 hp and a speed ratio up to 8 : 1, with some units even 12 : 1 and 15 : 1.

29. HYDRAULIC VARIABLE-SPEED DRIVES

There are two main systems of hydraulic variable-speed devices, the hydrostatic and the hydrodynamic types.

HYDROSTATIC TYPES use a variable displacement pump as a source of fluid power and a constant displacement or variable displacement hydraulic motor. Both pump and motor are of the piston type.

Power is transmitted by the fluid as a result of the pump delivery and the hydraulic pressure. The kinetic energy of the fluid is not used since it is very small because of the low velocity and small quantity involved; also, there is no change in velocity, the fluid leaving the motor with the same velocity as that with which it entered.

The main characteristics of the positive displacement piston-type variable-speed devices are as follows:

1. Output revolutions per minute varies directly as the volume rate of flow of fluid.

2. Assuming constant fluid pressure, motor torque is constant and horsepower varies proportionally with speed.

3. Torque is directly proportional to fluid pressure.

4. With a given volume of fluid, motor horsepower varies directly with fluid pressure. The drive can be laid out for constant horsepower, constant torque or any combination of the two.

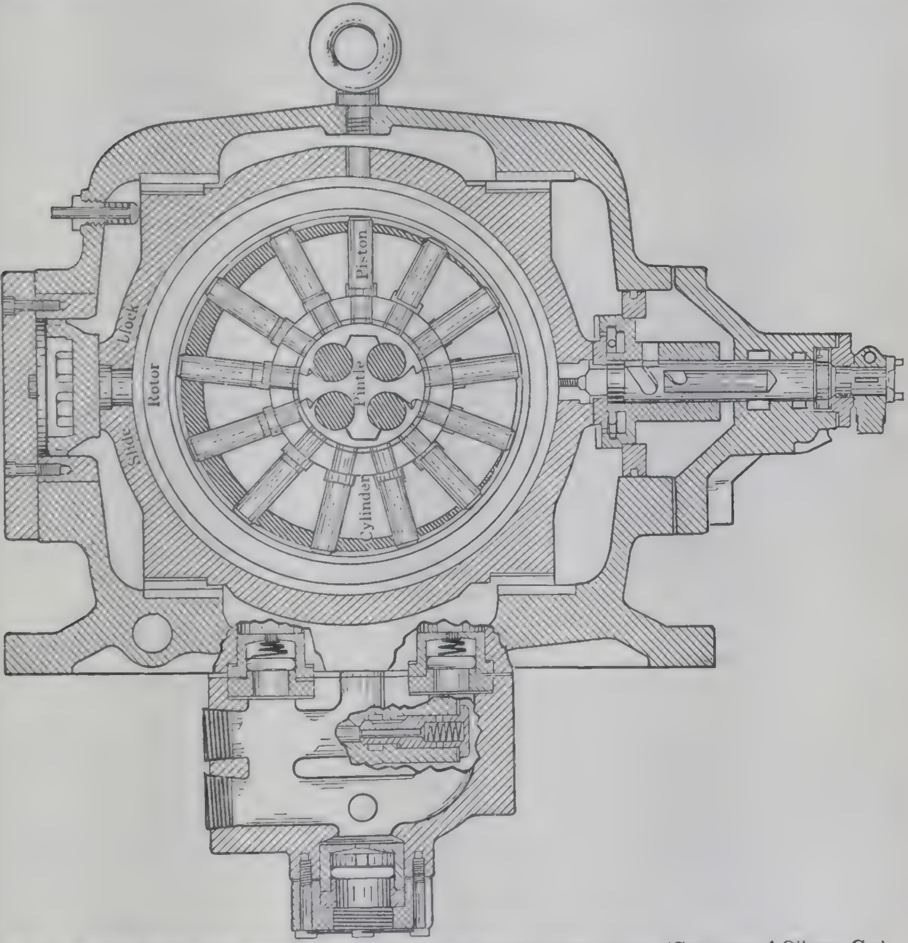

Fig. 6. Cross section through radial-piston variable-delivery pump. (Courtesy of Oilgear Co.)

5. Minimum speed depends on many factors, such as nature of source of fluid power, leakage, number of pistons, and type of load. In general, the usable minimum speed is somewhere between 1 and 30 rpm.

6. Torque efficiency is 80% or more and can easily reach 90% or more at rated pressure. It is substantially constant from stalled to full rated speed.

7. Although the delivery of a pump may be varied from zero to maximum displacement, it is not possible, owing to mechanical inefficiencies, to vary the displacement of a piston motor more than about 4 : 1. Therefore, the combination variable-displacement motor and constant-displacement pump is used in exceptional cases only.

8. The most outstanding feature of piston-type devices is their low inertia. The ratio of rated torque over inertia can hardly be exceeded by other methods. This system is one of the best for applications where rapid response or greatest reversal rate are essential.

9. This hydraulic drive has an inherent overload protection; it can be safely stalled under load.

A radial piston variable-delivery pump (Oilgear Co., Milwaukee, Wis.) is shown in Fig. 6 It consists essentially of a heavy-duty, multiple, radial rolling piston pumping unit, which delivers any volume from zero to maximum in either direction; an integral device for actuation of the slide block manually, hydraulically, or electrically to select the volume and direction of oil flow; a small low-pressure gear pump to supply oil for control operation, to lubricate the radial piston pump when operating in neutral and partially to supercharge the radial piston pump; and a drive shaft and housing assembly and associated relief and check valves, all compactly arranged in a sturdy case. The pintle is pressed into the case. The cylinder rotates on the closely fitted tapered pintle. The shaft drives the cylinder through a floating coupling. The pistons are closely fitted in the cylinder. Reaction rings in the rotor confine the pistons. The rotor is mounted on antifriction bearings in an adjustable-stroke slide block and is rotated with the cylinder through contact of the rolling piston against the reaction ring. The slide block is guided on four plates and carries the rotor from a point concentric with the cylinder to any eccentric point up to maximum stroke on either side of the cylinder center line. Two opposing pistons actuate the slide block hydraulically to a position selected by the helix on the control shaft.

In operation, the shaft drives the cylinder clockwise, and the spot contacts of the convex piston heads on the concave reaction rings cause the rotor to rotate at the same speed as the shaft. When the center lines of the cylinder and the rotor coincide, no reciprocating motion is imparted to the pistons as the unit rotates. Therefore no oil is delivered. As the slide block is moved to the left (see Fig. 6), reciprocating motion is imparted to the pistons so that those passing over the lower port in the pintle are delivering oil to that port while those passing over the upper ports are sucking or filling up with oil.

As the slide block is moved to the right of the cylinder center line, the pistons passing over the upper port in the pintle are delivering oil to that port and those passing over the lower port are sucking or filling up with oil. The position of the slide block is accurately controlled hydraulically through the helix-type control shaft and vertical hole in the large control piston. The oil delivery can be varied over a stepless range in either direction from zero to maximum.

The construction of the constant-displacement motor is similar to that of the variable-delivery pump except that the slide block is omitted and the rotor is mounted on antifriction bearings in the motor case and set at maximum stroke on one side of the cylinder center line. The available sizes of Oilgear transmissions and their ratings are shown in Table 4.

Table 4. Horsepower and Torque Ratings of Oilgear Hydraulic Variable-speed Transmissions

(The Oilgear Co., Milwaukee, Wis.)

* Assumes 4 ft of pipe between units. Values reduce by amount of additional pipe line losses if longer pipes are used.

An axial piston variable-speed transmission (Waterbury Tool Division of Vickers, Inc., Waterbury, Conn.) is shown in Fig. 7. It consists of a variable-displacement pump, called the A-End, and a constant displacement motor, called the B-End. These ends are of the positive displacement type, using oil as the hydraulic fluid, and may be closely coupled (Type C), as shown, or connected by external piping (Type K) at any angle, at any level, and over considerable distances.

The A-End is driven at constant speed by an electric motor or other prime mover. The output of B-End speed can be varied continuously from zero to the speed of the A-End in either direction. The rated torque can be transmitted at all speeds down to 1 rpm and can even be exerted at zero speed. Full torque loads can be rotated from a standstill position. These units are particularly adapted to carry accelerating and decelerating loads, and momentary shock or overloads.

The output shaft may be brought up to speed, or reversed, in a few seconds or less while carrying the load, according to the type of control used, which may be manual, rotary (as shown), sliding, lever, selsyn, servo, follow-up, and other hydraulic, electrical, or mechanical types.

In the A-End, an odd number of axially displaced pistons and ball-ended connecting rods are driven in and out of cylinders in a rotating cylinder barrel by a socket ring revolving in a plane inclined to the driving shaft. The socket ring is coupled to the shaft through a universal joint. The piston thrust is taken up by roller thrust and radial bearings mounted in a trunnioned box, which can be tilted by means of the controls. When the plane of the socket ring is vertical, the pump is in the neutral or off stroke position, and no pumping occurs. Movement of the control causes the tilting box and socket ring to tilt at an angle to the shaft. The pump is then on stroke, and pumping occurs in proportion to the angle of tilt. The tilting angle is limited to 20 degrees. The B-End is similar to the A-End, but it has the box fixed at 20 degrees.

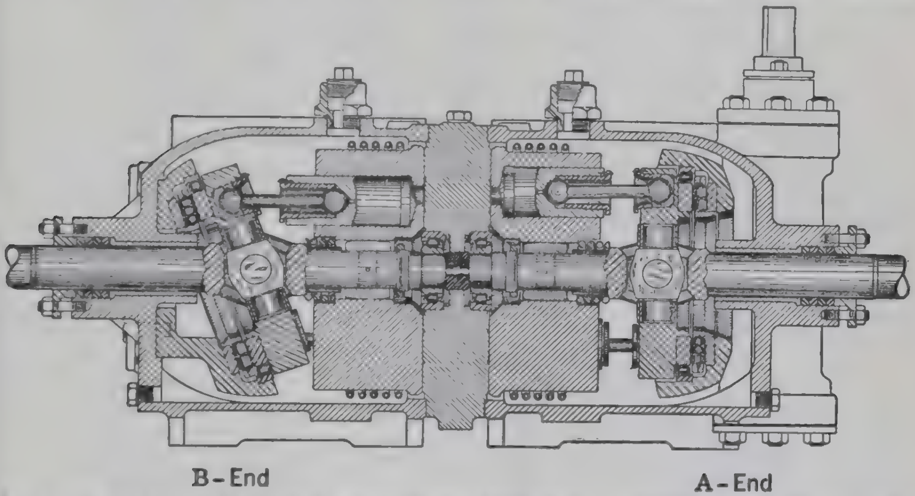

FIG. 7. Section through axial-piston variable-speed transmission. (Courtesy of Waterbury Tool Division of Vickers, Inc.)

Oil is pumped from elongated ports in the A-End cylinders into a common pressure port in a member, called the valve plate, against which the face of the cylinder barrel rotates. This pressure port is connected directly through the valve plate to the B-End cylinder barrel for closely coupled units, as shown, or by external piping to the B-End valve plate. The valving of the ports is done automatically by the valve plate design. The pressure oil pumped into the B-End acts on the pistons to impart a thrust through the connecting rods to the inclined socket ring, and, because of the inclination, causes the socket ring, and hence the output shaft, to rotate. The oil in the B-End cylinders is carried around to the low-pressure port of the valve plate and is pumped back into the A-End by the return stroke of the B-End pistons. The output speed depends on the volume of oil being pumped. Table 5 shows the available sizes, speeds, torque, and horsepower ratings of the Waterbury variable-speed transmission.

The transmissions described are representative of the field. Among other prominent manufacturers of this type of equipment are the following:

Vickers, Inc., Detroit, Mich. Variable-delivery piston-type pumps and constant- and variable-displacement motors from fractional to several hundred horsepower.

Northern Pump Company, Minneapolis, Minn. Variable-delivery piston-type pumps and constant-displacement motors from 1 to several hundred horsepower.

Sundstrand Pump Division, Rockford, Ill. Small sizes, variable-delivery piston-type pumps and constant-displacement motors up to 2 hp.

HYDRODYNAMIC TYPE. One development of this type is the variable-speed hydrodynamic fluid drive of the American Blower Corporation, Detroit, Mich.

Variable-speed fluid drives are intended for use with constant-speed a-c motors to provide stepless adjustment of speed for industrial machinery. These transmissions depend on

Table 5. Horsepower and Torque Ratings of Waterbury Hydraulic Variable-speed Transmissions

(Waterbury Tool Division of Vickers, Inc., Waterbury, Conn.)

Size No.	A-ends or Pump Units			B-ends or Motor Units		
	Horsepower Input at Normal Torque and Rate of Speed	Working Speed, rpm	Working Horsepower, Continuous Duty	Speed Range, rpm	Working Horsepower, Continuous Duty at Maximum Speeds	Working Torque, in.-lb
2	10	900	8	0–900	8	580
5	15	600	12	0–600	12	1,260
10	30	550	24	0–550	24	2,520

50	100	400	80	0–400	80	12,600
150	200	250	160	0–250	160	37,800
172	350	350	300	0–350	300	54,000

Note. The above normal working horsepower ratings are based on continuous 24-hr daily service. Intermittent ratings may be increased 25% and, for occasional services, more; for momentary overloads the working torque may be increased 150%.

turbine action of the fluid (oil) to transmit power. There are two rotors with straight radial vanes which form a torus ring, as illustrated in the cross section (Fig. 8). The impeller which is attached to the driving motor acts as a pump and sets up a vortex of oil (see arrow) which drives the runner smoothly and without mechanical means like a turbine wheel. The runner is connected to the driven machine.

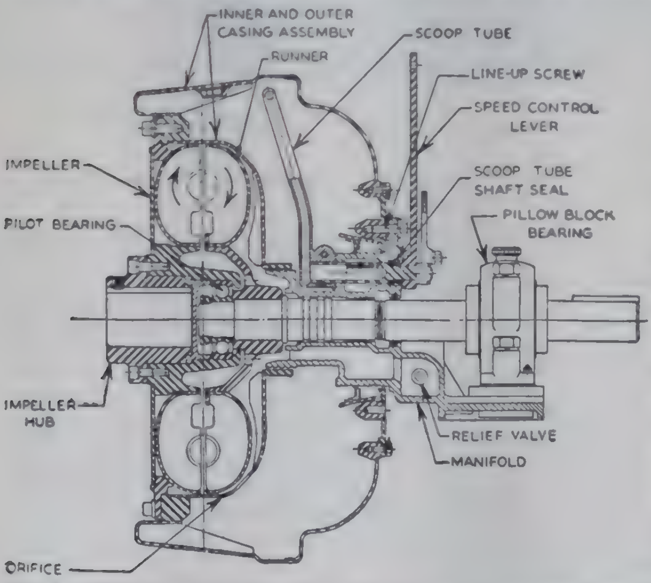

Fig. 8. Variable-speed fluid drive. (Courtesy of American Blower Corp.)

By changing the quantity of oil in the vortex, it is possible to adjust the output speed. The various means of adjusting oil quantity (and speed) are described below. The efficiency of power transmission when the drive is operating at full output speed is approximately 96 to 98%.

Lever-controlled Fluid Drive. This design (see Fig. 8) has a large rotating casing attached to the impeller, the purpose of the casing being to store (centrifugally) the idle oil which is not in the vortex between the runner and the impeller. A continuous flow of oil drains from the vortex into this casing through calibrated orifices (nozzles) and forms an annular ring. The rotating ring of oil impinges on a stationary scoop tube and is thus caused to flow through a cooler circuit and back into the vortex. The position of the scoop tube is adjusted by the external speed-control lever so that any desired amount of oil is carried in the vortex. By this means, speed is varied. Remote manual or automatic control devices are readily adaptable.

Field of Application. This unit is designed for machinery drives ranging from 5 to 350 hp. It is intended to be hub-mounted on the driving motor.

Pump-controlled Fluid Drive. This design has an external reservoir to store the oil which is not in the working circuit. To increase speed, a small oil pump transfers oil from the reservoir to the working circuit through a stationary manifold. Oil is removed by a stationary scoop tube inserted between the rotating casings and attached to the manifold. When no speed change is required, the scoop tube continually circulates oil through a cooler and back to the rotors, there being no change in the quantity of oil in the working circuit. But when a decrease in speed is required, the oil from the scoop tube can be diverted to the external reservoir (by a valve or by reversing the oil pump). The amount of oil in the rotors is thus decreased. It is a simple matter to adapt automatic control to operate the control pump or the valves.

Field of Application. This unit is designed for fan and centrifugal pump drives ranging from 100 to 2000 hp. It is also used for various machinery drives including rotary kilns, centrifugal compressors, and large test stands. It is a self-contained unit with its own supporting bearings. The input and output shafts are connected to the motor and driven machine by flexible couplings.

Enclosed Fluid Drive. This design has a stationary housing surrounding the rotors and the bearings. The bearings and the housing are split for inspection (or removal) of the rotors and shafts.

The essential differences between the control of this unit and the control of the other two designs are (1) the absence of nozzles to regulate the oil flow from the vortex and (2) the use of the oil pump to supply oil continuously to the rotors. The oil distributes itself centrifugally throughout the vortex *and* the space between the casings, forming an annular ring of fluid. The speed controller tube is inserted between the casings and acts as a weir as it skims off the rotating ring of oil according to its position. The speed controller thus sets the level of oil *in the vortex as well as in the casings* and controls output speed and torque. It discharges directly to the reservoir in the lower part of the housing. By fully inserting the speed controller, all the oil can be removed. Any degree of engagement is possible by adjusting its position. It is readily adaptable to automatic control.

Field of Application. The enclosed fluid drive is designed for drives of 100 hp and above, for power plant service (mechanical draft fans and boiler feed pumps), and for general industrial drives (centrifugal pumps and compressors, ball mills, test stands, etc.).

Ratings. In general, horsepower varies as $\overline{\text{rpm}}^3$ and $\overline{\text{diameter}}^5$. The horsepower capacity is taken with the normal slip of 3% or less between runner and impeller speeds.

The speed-control range of these fluid drives depends on the application. The speed can be varied as follows: (1) *Variable torque loads* (fans, centrifugal pumps, centrifugal compressors). The horsepower of the load falls off very rapidly (approximately $\overline{\text{rpm}}^3$) at reduced speeds. With this type of load, the output speed can be reduced to one-fifth the driving motor speed, or lower in special cases. (2) *Constant torque loads with high inertia and with negligible load fluctuation* (for example, printing presses). The output speed can be reduced to one-third the driving motor speed. By hand control, it is possible to run at lower speeds for short periods of time. (3) *Constant torque loads with some load fluctuations* (for example, rotary kilns). The output speed can be reduced to one-half the driving motor speed for normal operation, lower for starting duty only.

30. ELECTRICAL METHODS OF SPEED CONTROL

A great variety of electrical methods of speed control are available. In general, the electrical methods are convenient, simple, and reliable, provided that current, motor type, motor size, and control method are properly selected for the particular speed-torque characteristics and the speed range required.

Table 6 shows a brief survey of the conventional electrical systems of variable speed drives. For the sake of simplicity, methods not commonly used are omitted, as, for example, primary resistors and speed governors for fractional horsepower motors or intricate methods as the Scherbius, Kraemer, or Rosman system, which have been developed for special purposes and high power only. Furthermore, the list gives the characteristics for positive loads only; overhauling loads are not considered.

COMBINATION OF ELECTRICAL AND HYDRAULIC OR MECHANICAL METHODS. Frequently a convenient solution of a specific speed-control problem can be effected by combining one of the electrical methods with one of the other methods, for example, a combination of an electrical with a mechanical or an electrical with a hydraulic system. In this way, almost any required speed range or speed-torque characteristic can be achieved.

Table 6. Conventional Electrical Method of Speed Control

Motor Type	Method Used	Practical Speed Range, Basic Speed = 100%	Regulation Adjusted Speed	Rated Torque at Changed Speed	Efficiency	Notes
D-c series	Series resistance	20–100	Varies	Constant	Low	
D-c series	Series resistance Arm shunt	10–100	Varies	Constant	Low	
D-c series	Field shunt	100–130	Varies	Decreases with speed increase	High	Limited by commutation
D-c shunt or compound	Series resistance	20–100	Varies	Constant	Low	
D-c series	Two-motor series, parallel	50–100	Varies	Constant	High	
D-c shunt or compound	Field control	100–400	Constant	Decreases with speed increase	High	Conventional design
D-c shunt or compound	Field control	100–800	Constant	Decreases with speed increase	High	Special field structure Westinghouse *
A-c polyphase squirrel cage	By frequency and voltage change	10–400 or more	Constant	Constant	High	Maximum speed limited by mechanical conditions
A-c polyphase squirrel cage	Consequent poles	50, 100	Constant	Constant torque or constant horsepower or variable torque	High	Two speeds
A-c polyphase squirrel cage	Two windings and consequent poles	33, 66, 100, 200	Constant	Constant torque or constant horsepower or variable torque	High	Four speeds - other ranges possible
A-c polyphase wound rotor	Secondary resistance	25–100	Varies	Constant	Low	
A-c polyphase wound rotor	Two motors in concatenation	25–100	Constant	Constant	High	Just four economic speeds
A-c supply conversion to variable voltage and d-c shunt motors	By variable voltage	10–100	Fairly constant	Constant	High	Conventional
	By field control	100–400	Constant	Decrease with speed increase		
	By variable voltage	5–100	Constant	Constant	High	Using regulating exciters and closed cycle speed control
	By field control	100–400	Constant	Decrease with speed increase		
A-c polyphase shunt (Schraege)	Brush shifting	25–100	Fairly constant	Constant	High	

---

HYDRAULIC TORQUE CONVERTERS

The hydraulic torque converter is a power transmission element which provides an output speed which varies with the torque requirements. The speed ratio is controlled not by the operator but automatically by the torque. To obtain accurate control over output speed, therefore, the torque converter must be used with a variable-speed driving element such as an internal combustion engine.

In its simplest form the hydraulic torque converter consists of three elements: a pump, a turbine, and a reaction member (stator)(Fig.1). The pump element, which corresponds to the impeller of a centrifugal pump, delivers hydraulic fluid to the turbine runner, in which the fluid flows radially inward. Fluid leaving the turbine flows through a series of guide vanes in the stationary reaction member and again enters the pump. This stationary reaction member is an essential feature of a torque converter. By redirecting the flow of fluid, it absorbs the difference between the input and output torques, and without it no change in torque could be effected.

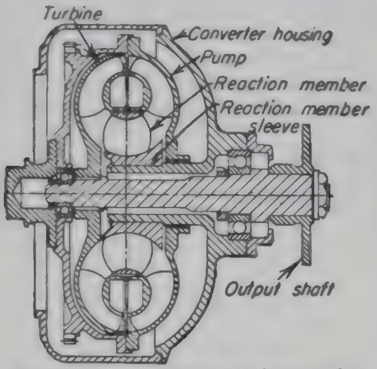

FIG. 1. Three-element single-stage hydraulic torque converter. (Reproduced by permission from *Machine Design*, May 1946)

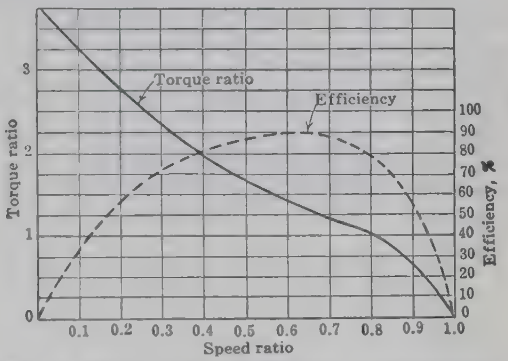

FIG. 2. Torque ratio and efficiency of three-element single-stage hydraulic torque converter. (Reproduced by permission from *Machine Design*, May 1946)

Performance of a torque converter such as shown in Fig. 1 may be represented by a pair of curves showing efficiency and torque ratio plotted against speed ratio (Fig. 2). These three quantities are related by the equation

$$\frac{T_2}{T_1} = \frac{N_1}{N_2} \times \frac{e}{100}$$

where T_2/T_1 is the ratio of output to input torques; N_2/N_1 is the ratio of output to input speeds; and e is the efficiency. The actual torque capacity is roughly proportional to the square of the input speed and to the fifth power of the converter diameter. It is also affected by the speed ratio, as shown in Fig. 3, in which primary torque is defined as the input torque required to maintain constant input speed.

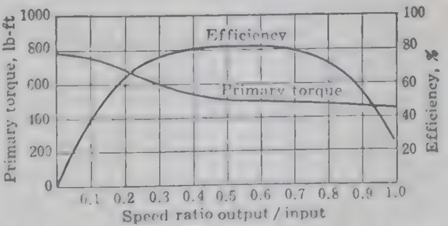

FIG. 3. Primary torque and efficiency of a three-stage hydraulic torque converter. (Reproduced by permission from *Machine Design*, April 1948)

As Fig. 2 shows, torque multiplication is maximum at zero output speed (the runner being stalled). As output speed increases, torque ratio falls off until at a certain speed ratio which usually lies between 0.65 and 0.85, depending on the design, it becomes unity. This is called the "clutch point" because under this condition the converter acts merely as a coupling or fluid clutch; there is no torque conversion and no torque reaction on the stationary member.

If the speed ratio were allowed to exceed that at the clutch point, the torque ratio
would drop below unity and torque reaction on the stationary member would be negative.
If it is desired to operate above this point, the resulting loss of power may be avoided by
doing either of two things: The reaction member may be "cut loose" so that it is free to
revolve with the fluid and exerts no drag; or the input and output shafts may be directly

coupled mechanically, thus by-passing the converter. In the first method the stator is mounted on a free-wheeling clutch which automatically allows it to revolve in the direction of motion as soon as the torque reaction reverses direction. Above the clutch point, therefore, the unit functions as a fluid coupling, and its efficiency is practically equal to the speed ratio.

Many combinations of torque converter elements with clutches and gears, including planetary gears, are possible, permitting a wide variety of torque and speed characteristics. Chief applications are in conjunction with internal combustion engines. The result is a drive which is highly flexible, both as to output speed and output torque, and which is well adapted to such service as automotive, hoisting, oil-well drilling, etc.

Torque multiplication can be increased by using multistage elements in place of the single stage shown in Fig. 1. To increase the speed range over which high efficiency can be maintained, the stator and turbine elements may be split into two or more sections, some of which are free to freewheel whenever torque reaction becomes zero. In this way the angle through which the element diverts the fluid adjusts itself according to the requirements imposed by the torque-speed relationships, a larger angle being required at high ratios.

Hydraulic torque converters available for industrial uses include the Lysholm-Smith three-stage unit (made by the Twin Disc Clutch Co., Racine, Wis.) and the Schneider single-stage unit (made by the Torcon Corp., Chagrin Falls, Ohio).

ELECTRIC MOTORS AND THEIR CONTROL

1. DEFINITIONS

ALTERNATING CURRENT. A current that alternately increases and decreases in magnitude with respect to time, whose values recur at equal intervals of time and whose average value is zero. Abbreviation, a-c.

ARMATURE. The part of a dynamoelectric machine that includes the main current-carrying winding. In d-c machines and in a-c commutator machines, the armature winding is connected to the commutator, and the armature is the rotating member. In a-c machines without commutators, the armature may be either the rotating member or the stationary member.

ASYNCHRONOUS MACHINE. A dynamo-electric machine in which the speed of operation is not exactly proportional to the frequency of the system to which it is connected.

AUTOMATIC TRIPPING. The opening of a circuit breaker under predetermined or other conditions without the intervention of an operator.

AUTOTRANSFORMER. A form of transformer that has one continuous winding, part of which is common to both primary and secondary circuits.

BRANCH CIRCUIT. That portion of a wiring system extending beyond the final automatic overload protective device of the circuit.

CAPACITOR (Static Condenser). A device whose primary purpose is to store electric charges. It commonly is used in a-c circuits to change the relative time phase between voltage applied and current flowing in the circuit. The usual form consists of two conducting plates, usually of aluminum foil, separated by a thin layer of insulation (dielectric), the combination being hermetically sealed in a steel container.

CIRCUIT BREAKER. A device for interrupting a circuit between separable contacts under normal or abnormal conditions. Ordinarily circuit breakers are required to operate only infrequently, although some classes of breakers are suitable for frequent operation.

CIRCULAR MIL. The area of a circle of 1-mil diameter, or $(\pi/4) \times (0.001)^2$ sq in. = 0.000 000 7854 sq in.

CLASS A INSULATION consists of: (1) cotton, silk, paper, and similar organic materials when either impregnated or immersed in a liquid dielectric; (2) molded and laminated materials with cellulose filler, phenolic resins, and other resins of similar properties; (3) films and sheets of cellulose acetate and other cellulose derivatives of similar properties; and (4) varnishes (enamel) as applied to conductors.

CLASS B INSULATION consists of inorganic materials, such as mica and asbestos in built-up form, combined with binding substances. If Class A material is used in small quantities in conjunction with Class B, for structural purposes only, the combined material may be considered Class B, provided the electrical and mechanical properties of the insulated winding are not impaired by the application of the temperature permitted for Class B material. (The word "impair" is here used in the sense of causing any change that could disqualify the insulating material for continuous service.)

CLASS C INSULATION consists of inorganic materials such as pure mica, porcelain, quartz, etc.

CLASS H INSULATION consists of (1) mica, asbestos, Fiberglas, and similar inorganic materials in built-up form with binding substances composed of silicone compounds, or materials with equivalent properties; (2) silicone compounds in rubbery or resinous forms, or materials with equivalent properties. A minute proportion of Class A materials may be had only where essential for structural purposes during manufacture, providing the electrical and mechanical properties of the insulated winding are not impaired by the application of the temperature permitted for Class H material.

CLASS O INSULATION consists of cotton, silk, paper, and similar organic materials when neither impregnated nor oil-immersed.

COMMUTATING POLE (Interpole). An auxiliary pole placed between the main poles of a commutating dynamoelectric machine. Its exciting winding carries a current proportional to the load current and produces a flux in such a direction and phase as to assist the reversal of current in the short-circuited coil.

COMMUTATOR. An annular ring or disk assembly of conducting members, individually insulated in a supporting structure, with an exposed surface for contact with current-collecting brushes, and ready for mounting on an armature spider, shaft, or quill.

CONTROLLER. A device, or group of devices, that governs, in some predetermined manner, the electric power delivered to the apparatus to which it is connected.

DIRECT CURRENT. A unidirectional current in which the changes in value are either zero or so small that they may be neglected. Abbreviation, d-c.

EFFICIENCY of a device with respect to a physical quantity that may be stored, transferred, or transformed by the device is the ratio of the useful output of the quantity to its total input. Unless specifically stated otherwise, the term *efficiency* means efficiency with respect to power.

ELECTRICAL DEGREE. The 360th part of the angle subtended, at the axis of the machine, by two consecutive field poles of like polarity. One *mechanical degree* is thus equal to as many electrical degrees as there are pairs of poles in the machine.

EXCITER. An auxiliary generator that supplies electric current to excite the field of another electrical machine.

FREQUENCY, of an Alternating Current. The number of cycles through which the current passes per second; frequency is the reciprocal of the *period*.

GENERATOR, Double-current. A machine that supplies both direct and alternating currents from the same armature.

GENERATOR, Electric. A machine that transforms mechanical energy to electrical energy.

GENERATOR, Induction. An induction machine (see below) driven above synchronous speed by an external source of mechanical power, and returning energy to the circuit.

GENERATOR, Magnetoelectric. An electric generator, the field poles of which are permanent magnets.

GENERATOR, Synchronous. A synchronous machine that transforms mechanical power into electric power.

GROUND. A conducting connection, whether intentional or accidental, between an electric circuit or equipment and earth, or to some conducting body that serves in place of the earth.

INDUCTION MACHINE. An asynchronous a-c machine that comprises a magnetic circuit interlinked with two electric circuits, rotating with respect to each other, and in which power is transferred from one circuit to another by electromagnetic induction. Examples of induction machines are induction motors, induction generators, and certain types of frequency converters and phase converters.

KILOWATT. A unit of electrical power equal to 1000 watts or 1.34 hp.

KILOWATT-HOUR. The work performed by 1 kw acting for 1 hr.

LOAD FACTOR. The ratio of the average load over a designated period to the peak load occurring in that period.

MAGNETIC CONTROLLER. A controller all of whose basic functions are performed by electromagnets.

MANUAL CONTROLLER. A controller all of whose basic functions are performed by hand.

MOTOR, Adjustable-speed. See pp. 16-12, 16-51.

MOTOR, Capacitor. See pp. 16-21, 16-26.

MOTOR, Capacitor-start. See p. 16-21.

MOTOR, Compound-wound. A d-c motor with two separate field windings connected—*a*, in parallel with the armature circuit, and, *b*, in series with the armature circuit. Winding *a* usually is the predominant field.

MOTOR, Constant-speed. See p. 16-12.

MOTOR, General-purpose. Any motor of 200 hp or less and 450 rpm or more, having a continuous rating, and designed, listed, or offered in standard ratings for use without restriction to a particular application.

MOTOR, Induction. An induction machine that converts electrical energy delivered to the primary circuit into mechanical energy by the electromagnetic interaction between the primary and secondary circuits. The secondary circuit is short-circuited or closed through a suitable circuit.

MOTOR, Large-power (Integral Horsepower). A motor built in a frame having a continuous rating of 1 hp, open type, at 1700–1800 rpm or in a larger frame.

MOTOR, Nonexcited Synchronous. A synchronous motor without a d-c field winding.

MOTOR, Permanent-split Capacitor. See p. 16-21.

MOTOR, Reactor-start. A form of split-phase motor (see below) designed to start with a reactor in series with the main winding. The reactor is short-circuited or otherwise made ineffective, and the auxiliary circuit is opened when the motor has attained a predetermined speed.

MOTOR, Repulsion. A single-phase a-c motor with a stator winding arranged for connection to the source of supply, and a rotor winding connected to a commutator. Brushes on the commutator are short-circuited and so set that the line connecting the positive and negative brushes is at an angle to the neutral axis of the stator winding. This type of motor has a varying speed characteristic.

MOTOR, Repulsion-induction. A form of repulsion motor which has a squirrel-cage winding in the rotor, in addition to the repulsion motor winding. This type of motor may have constant speed or varying speed characteristics. See pp. 16–21, 16–26.

MOTOR, Repulsion-start Induction. A single-phase motor having the same windings as a repulsion motor, but in which, at a predetermined speed, the rotor winding is short-circuited or otherwise connected to give the equivalent of a squirrel-cage winding. This type of motor starts as a repulsion motor but operates as an induction motor with constant speed characteristics. See pp. 16–21, 16–26.

MOTOR, Resistance-start. A form of split-phase motor (see below) with a resistance connected in series with the auxiliary winding. The auxiliary circuit is opened when the motor has attained a predetermined speed.

MOTOR, Series-wound. A commutator motor in which the field circuit and armature circuit are connected in series.

MOTOR, Shaded-pole. See p. 16-21.

MOTOR, Shunt-wound. A d-c motor in which the field circuit and armature circuit are connected in parallel.

MOTOR, Slip-ring. See Motor, wound-rotor induction.

MOTOR, Small-power (Fractional Horsepower). A motor built in a frame smaller than that having a continuous rating of 1 hp, open type, at 1700–1800 rpm.

MOTOR, Special-purpose. An industrial power motor specifically designated and listed for a particular power application, where load requirements and duty cycle are definitely known.

MOTOR, Split-phase. A single-phase induction motor equipped with an auxiliary winding, which is displaced in magnetic position from, and connected in parallel with, the main winding. The auxiliary circuit is opened when the motor has attained a predetermined speed. See p. 16-21.

NOTE: The term split-phase motor, when unqualified, describes a motor to be used without impedance other than that offered by the motor windings themselves.

MOTOR, Squirrel-cage Induction. An induction motor in which the secondary circuit consists of conductors suitably disposed in slots in the secondary core. See pp. 16–22, 16–35.

MOTOR, Synchronous. A synchronous machine that transforms a-c electrical power to mechanical power, and that has a speed strictly proportional to the frequency of the operating current. See p. 16-22.

MOTOR, Synchronous Induction. A wound-rotor induction motor to which d-c excitation is supplied when it approaches rated speed, enabling it to start as an induction motor and operate as a synchronous motor. See pp. 16–22, 16–47.

MOTOR, Two-value Capacitor. See p. 16-21.

MOTOR, Universal. A series-wound or compensated series-wound motor that will operate either on direct current or single-phase alternating current (of approximately the same voltage and a frequency not greater than 60 cps) at approximately the same speed and output. See p. 16-22.

MOTOR, Wound-rotor Induction. An induction motor in which the secondary circuit consists of a polyphase winding, or coils whose terminals are short-circuited or closed through suitable circuits. (When provided with collector or slip rings, a wound-rotor induction motor also is known as a slip-ring induction motor.) See p. 16-37.

OPEN MACHINE (or Motor). A self-ventilated machine having no restriction to ventilation other than that necessitated by mechanical construction.

POWER. The rate of transfer of energy. In the case of an a-c circuit the word power generally denotes the average value of the power over a cycle. The power in an electric circuit at any instant is equal to the product of the values of the current and voltage at that instant, and generally is called instantaneous power.

POWER FACTOR. The ratio of the power to the apparent power, that is, kw/kva. The maximum power factor is 1 or unity. It may be lagging or leading, depending on whether the current wave lags or leads the voltage wave. See *Power* Volume of Kent's *Mechanical Engineers' Handbook*, Section 16, Articles 12 and 13.

-PROOF (as a suffix). A machine (or apparatus) is designated as splashproof, moistureproof, explosionproof, etc., when so constructed, protected, or treated that subjection to the specified material or condition will not interfere with its successful operation.

RATING of a Machine, Apparatus, or Device. A designated limit of operating characteristics based on definite conditions. Such operating characteristics as load, voltage, frequency, etc., may be given in the rating.

RATING, Continuous. The rating that defines the load which can be carried for an indefinitely long time.

RATING, Short-time. The rating that defines the load which can be carried for a short and definitely specified time, the machine, apparatus, or device being at approximately room temperature at the time load is applied.

-RESISTING (as a suffix). A machine (or apparatus) is designated as moisture-resisting, fume-resisting, etc., when so constructed, protected, or treated that it will not be readily injured when subjected to the specified material.

SEMIMAGNETIC CONTROLLER. A controller having part of its basic functions performed by electromagnets and part by other means.

SINGLE-PHASE CIRCUIT. A circuit energized by a single alternating electromotive force. (A single-phase circuit usually comprises two wires. The currents in these two wires, counted outwards from the source, differ in phase by 180 degrees or a half cycle.)

SLIP (of an Induction Machine). The ratio, expressed as a percentage, of the difference between operating speed and synchronous speed to the synchronous speed.

SWITCH, General Use. A switch for general distribution and branch circuits. It is rated in amperes and is capable of interrupting its rated current at its rated voltage.

SWITCH, Isolating. A switch for isolating a circuit from its source of power. It is to be operated only when the circuit has been opened by some other means.

SWITCH, Motor-circuit. A switch for a motor branch circuit. It is rated in horsepower and is capable of interrupting the maximum operating overload current of a motor of the same horsepower at the rated voltage. The maximum operating overload of a-c motors is six times the rated current, and of d-c motors is four times the rated current.

SYNCHRONOUS MACHINE. A dynamoelectric machine in which the speed of normal operation is exactly proportional to the frequency of the current.

THREE-PHASE CIRCUIT. A combination of circuits energized by alternating electromotive forces that differ in phase by one-third of a cycle, i.e., 120 degrees.

-TIGHT (as a suffix). A machine is designated as watertight, dust-tight, etc., when so constructed that the enclosing case will exclude the specified material.

TORQUE. See p. 16-14.

TWO-PHASE CIRCUIT. A combination of circuits energized by alternating electromotive forces that differ in phase by a quarter of a cycle; i.e., 90 degrees.

UNDERVOLTAGE PROTECTION. The effect of a device, operative on the reduction or failure of voltage, to cause and maintain the interruption of power to the main circuit.

UNDERVOLTAGE PROTECTION, Time-delay. The effect of a device, operative on the reduction or failure of voltage for a definite period of time, to cause and maintain the interruption of power to the main circuit.

UNDERVOLTAGE RELEASE. The effect of a device, operative on the reduction or failure of voltage, to cause the interruption of power to the main circuit, but not to prevent the re-establishment of the main circuit on return of voltage.

2. APPLICATION OF MOTORS AND CONTROL

FACTORS AFFECTING MOTOR SELECTION. The various factors to be considered in selecting a motor and controller for a given application are summarized and discussed on pp. 16-06 to 16-10. These are broadly classified in accordance with their relation to (1) power supply, (2) driven machine, and (3) location.

Power Supply

- Characteristics
  - D-c—voltage
  - A-c—voltage, phases and frequency
- Power rates
  - Energy charge
  - Power-factor clause
  - Demand charge
- Voltage regulation
  - Starting current
  - Current pulsation
- Continuity of power
- Short-circuit current
- Voltage surges

Driven Machine

- Mechanical arrangement
  - Horizontal or vertical shaft
  - Tilting and rolling
  - Inverted operation
  - Stationary or portable
  - Method of connecting motor: direct-connected, built-in, belt, chain, or gear drive
  - Space limitations
- Speed, speed range, regulation
- Direction of rotation, reversing
- Synchronized operation
- Horsepower, rms, peak
- Torques
  - Breakaway, accelerating, pull-in
  - Torque pulsation
- Wk^2 of rotating parts
- Thrust
- Balance
- End play
- Frequency of starting
- Deceleration
- Operating schedule
- Initiation of operating sequence

Location

- Ambient temperature
- Altitude
- Surrounding atmosphere
  - Moisture
  - Dust
  - Corrosive or solvent
  - Hazardous dust or gas
  - Outdoor conditions
- Underwater operation
- Effect of noise
- Codes and ordinances

Power Supply

VOLTAGE of a d-c power supply and voltage, number of phases, and frequency of an a-c power supply must be known in order to select a correspondingly rated motor and controller. In most cases these conditions are fixed and readily determined. However, sometimes a choice is available or a conversion from one set of conditions to another is desirable. For example, for economical use of small motors it often is necessary to convert a high a-c voltage to a lower value by means of transformers. Again, in some applications, as those involving operation over a wide speed range or severe reversing duty, it is desirable to convert alternating current to direct current, by means of a motor-generator set or a rectifier, to allow the use of d-c motors.

POWER RATES may affect the choice of motor and controller, since the efficiencies of various types of motor differ appreciably, which means a corresponding difference in the power used. This is particularly true of adjustable speed motors with wide variations in efficiency, which must be balanced against wide differences in cost. Many a-c power-rate schedules incorporate a *power-factor clause*, by which the billing is adjusted in accordance with the power factor of the current. This may affect the choice of motor. For example, it may justify the selection of a synchronous motor instead of an induction motor. Finally, most rate schedules embody a *demand charge;* that is, the maximum rate at which energy is used for a given period of time, as well as the total amount consumed, determines the power bill. This fact makes it desirable to maintain as uniform a load as possible at all times. In some applications it will justify the use of an adjustable-speed or multi-speed motor instead of a constant-speed machine. See Purchased Power in Industry, Article 1, and Power Factor Improvement, Articles 12 and 13, in Section 16 of the *Power* Volume of Kent's *Mechanical Engineers' Handbook*.

VOLTAGE REGULATION of the power supply represents the drop in voltage that occurs with a certain increase in the current drawn. This must be considered, first, because the torques developed by motors vary with the impressed voltage, so that the actual voltage at the motor terminals under the various operating conditions must be known. With a-c motors, the starting torques vary as the square of the voltage. Since these motors draw a relatively high starting current, the effect of the voltage regulation of the power supply is particularly important. Second, if lights are supplied from the same power circuit, a drop in voltage of about 2% causes a noticeable flicker of these lights. Finally, a drop in voltage of 30% or more may cause other motors on the system to stall or be disconnected from the line by their undervoltage protective device. Power companies usually establish limits to the starting current that can be drawn from the line by motors, in order to prevent excessive drop in line voltage. These factors often necessitate reduced-voltage controllers where full-voltage starting otherwise would be acceptable. In some cases, a different type of motor must be used—for example, a wound-rotor induction motor instead of a squirrel-cage induction motor—in order to obtain sufficient starting torque while keeping within the allowable starting current.

Pulsating Current. When the load is such that the motor draws a pulsating current from the line, corresponding variations in line voltage occur. If these have a frequency lying in a certain range (see Fig. 1), they can be of very small magnitude and yet produce a noticeable flickering of lights supplied from the circuit. The usual limit established for current pulsation is 66% of motor full-load current. This usually does not cause light flicker, but sometimes the regulation of the system may require a much lower limit of pulsation, such as 30 or 40%.

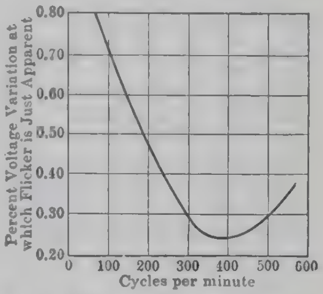

FIG. 1. Voltage variation causing light flicker at various frequencies.

CONTINUITY OF POWER SUPPLY may affect the choice of motors and control. Thus, if momentary interruptions or *dips* in line voltage are likely to occur, the use of time-delay rather than instantaneous undervoltage protection may be justified. See p. 16-59. In special cases, control equipment may be required that automatically will transfer the motor from one source of power to another, in the event of failure of the first.

SHORT-CIRCUIT CURRENT of the power system may affect the choice of control equipment. The line switch of a controller must be capable of interrupting the short-circuit current or must withstand this current without damage until it is interrupted by a circuit breaker or fuses connected between the power source and the controller.

VOLTAGE SURGES. When a motor is supplied from overhead power lines, either directly or through a transformer, lightning disturbances in the surrounding area may produce dangerous voltage surges at the motor terminals. Lightning arresters and surge protective capacitors may be required to protect the motor insulation. Direct-current motors on trolley circuits may be subjected to momentary overvoltages that require special design or external protective equipment.

Driven Machine

MECHANICAL ARRANGEMENT of the driven machine is the first consideration. Whether it is driven through a horizontal or a vertical shaft determines which of these two types of motor should be selected. Horizontal motors are more generally available and less expensive. Most grease-lubricated ball-bearing motors and small-power motors with waste-packed sleeve bearings will operate in either position.

Motors operated with a tilted shaft, if the tilt is momentary, require special construction of sleeve-bearing housings and, for long periods of tilted operation, may need bearings suitable for end thrust. If the motor operates with a roll (changing angle around horizontal shaft) of more than 10 or 12 degrees, a ball-bearing machine is usually necessary. Within this angle sleeve-bearing motors with modified oil gages are applicable.

Method of connecting motor to the driven machine must be considered. If the speed corresponds to that of an economical motor speed, a direct-connected motor normally is used. Otherwise, speed transformation by belt, chain, or gears must be employed. Maintenance, efficiency, and space requirements as well as initial cost enter into this choice. A direct-connected motor economically may be *built-in*. This type usually involves a special motor without shaft or bearings, arranged to be mounted on the shaft of the driven machine. Occasionally, the motor stator also is arranged to be supported from the driven machine. Compactness is one of the principal advantages of this construction. When the motor drives through a flat belt, multiple-V-belt, or chain, the dimensions of pulleys or sprockets and the center distance must be known in order to determine the side pull on the motor shaft. In some cases, the motor must have an extended shaft and outboard bearing to limit bearing pressure and shaft deflection. A sliding base or other means for adjusting the position of the motor to maintain proper tension in the driving member is necessary with belt or chain drive.

Space available may affect the choice of motor. If space is limited, a direct-connected or built-in motor usually is most suitable. Where the speed of the driven machine prohibits this choice, a gear motor often is the best solution. In some cases forced ventilation of a motor by an external blower may effectively reduce the motor size. Similar results may be obtained from a motor with Class B insulation, operating at a correspondingly higher temperature rise.

SPEEDS. The operating speed, speeds, or speed range of the driven machine must be known in order to select a corresponding single-speed, multispeed, or adjustable-speed motor. If the machine operates at a single speed, any type of motor may be used, the choice depending on other factors. When two, three, or four fixed speeds bearing the proper ratio to each other are acceptable, a multispeed squirrel-cage induction motor may meet the requirements. If the speed range does not exceed 2 : 1 and a reasonable number of speed points is satisfactory, and if considerable variation in speed with load is not detrimental, the wound-rotor induction motor should be considered. For more severe requirements a d-c motor with field or variable-voltage control, or an a-c adjustable-speed, brush-shifting motor may be necessary.

Speed Regulation. The allowable speed regulation (variation in speed with load) may determine the type of motor, particularly when adjustable speed operation is involved. For most single-speed applications, the squirrel-cage induction motor or shunt-wound d-c motor is satisfactory, but in a few applications zero speed regulation is required. This necessitates a synchronous motor. For adjustable-speed service, the wound-rotor induction motor and the d-c motor with armature resistance control often are eliminated because of their high-speed regulation.

DIRECTION OF ROTATION. Certain types of motors require adjustment or reconnection of windings to change the direction of rotation, which can be most conveniently done in the factory. Hence, the direction of rotation should be specified. If the motor is to run in both directions, a motor suitable for reversing and a reversing controller must be provided.

SYNCHRONIZED OPERATION. Sometimes two or more widely separated motor-driven machines must be kept in synchronism, i.e., must operate as if their shafts were directly coupled. This synchronization may require power selsyns (a wound-rotor induction motor on each drive with their rotor windings connected in parallel) in addition to the driving motors. In other cases, two or more motors must operate over a wide speed range but with a fixed ratio maintained between the speeds of the various motors. This operation usually requires adjustable-speed motors with suitable automatic control for maintaining the desired speed relationship.

HORSEPOWER required to drive the load determines the motor rating. Where the load is not constant but varies with time, the complete duty cycle (horsepower vs. time curve) should be obtained. From this curve, the peak horsepower, which determines the maximum torque of motor, and the root-mean-square (rms) horsepower can be calculated. The latter is the square root of the mean value (averaged against time) of the square of the horsepower needed. It is an approximate indication of the horsepower rating of the driving motor required from the standpoint of heating. However, where large variations in load occur or where the motor is shut down, accelerating or decelerating an appreciable portion of the time, the rms horsepower does not necessarily give a true indication of the equivalent continuous load, and it is advisable to consult the motor manufacturer. If the load continues at a certain value for an extended period of time (15 min to 2 hr, depending on the size of the motor), the horsepower rating of the motor should be not less than this value, regardless of any subsequent reduction in load. Where the motor operates at more than one speed, the horsepower required at each speed must, of course, be known.

TORQUES necessary to start and drive a load deserve careful consideration. Of particular importance is the breakaway torque requirement, since this often is considerably higher than the running torque. Furthermore, reduced-voltage starting may be necessary to meet starting current limitations, and this reduces the torque delivered by the motor. Where a synchronous motor is being considered, the torque required at full speed under starting conditions is equally important, since it determines the pull-in torque. Pull-in torque is not necessarily equal to full-load torque, as the machine may be unloaded for starting or may be required to start when the load is temporarily higher than normal. It is often desirable or essential to know the load torque at all speeds from standstill to full speed (speed-torque curve). This affects the accelerating time and hence the heating of the motor and control equipment. In particular, squirrel-cage induction motors, synchronous motors, and starting resistors, reactors, and autotransformers may have to be of special design if the accelerating time is unusually long. Where reduced-voltage starting is employed, the speed-torque curve of the load determines the speed to which the motor will accelerate on reduced voltage and hence determines the current inrush when the motor is transferred to full voltage.

Running Torque. The horsepower required and the speed of the driven machine determine the running torque. Certain driven machines, of which reciprocating compressors are typical, have a load torque which pulsates periodically. To prevent excessive pulsation in the current drawn by the motor proper, flywheel effect, Wk^2, must be provided in the motor or driven machine. With synchronous motor drives, the flywheel effect must be such that the natural frequency of the motor is not close to the frequency of any impulses in the load torque. The former can be calculated as follows: Let F = natural frequency of motor, cycles per minute; Wk^2 = (weight, pounds) × (radius of gyration, feet)^2 of the rotating parts of motor and load; N = revolutions per minute of motor; f = line frequency; and P_r = synchronizing power of motor, kilowatts per electrical radian. Then $F = (35{,}200/N)\sqrt{(P_r \times f)/Wk^2}$.

Wk^2 OF THE ROTATING PARTS of the driven machine affects the accelerating time and hence affects the heating during the starting period of motors and control equipment. Its value is particularly important when the motor is started frequently or when reversing duty is involved. The Wk^2 always should be known if a synchronous motor is to be employed, since the pull-in torque of the motor varies approximately as the square root of the total Wk^2 of motor and load. If a rotating member of the driven machine operates at a different speed from that of the motor, its Wk^2 can be converted to an equivalent value at the motor shaft by multiplying by

$$\left(\frac{\text{Rpm of rotating member}}{\text{Rpm of motor}}\right)^2$$

THRUST. Some driven machines (certain types of pumps and fans are typical) impose a thrust on the motor in a direction parallel to the shaft. Horizontal motors with thrust bearings may be required. Vertical motors may need an oversized thrust bearing if considerable external thrust is imposed.

BALANCE. Some driven machines such as precision grinders require motors specially balanced to give very small amplitudes of vibration.

END PLAY. Certain driven machines require motors with limited or zero end play and may need motors with preloaded ball bearings or sleeve bearings with end-play limiting devices.

FREQUENCY OF STARTING may affect the choice of motor and controller, since each start results in additional heating of the motor windings, starting resistors, etc. This must be considered in connection with the load torques and load Wk^2, which determine the accelerating time and hence the heating during each start.

In some applications, **rapid deceleration** of the motor and load is essential. With induction motors it may be necessary to provide *plugging control*, and with synchronous or d-c motors, dynamic braking control (see p. 16-64).

Plugging consists of reversing two leads of a motor while the motor is running, so as to reverse the phase rotation. The control thus is similar to that provided for reversing service. A relay, mounted on the motor shaft, usually is included to disconnect the motor from the line when it stops and to prevent it from starting in the reverse direction.

THE OPERATING SCHEDULE of a machine, i.e., the total number of hours of operation per year, should be known. If this figure is high, motors having maximum efficiency are more readily justified. If the load or speed varies, the operating time under each condition should be considered in order to permit proper evaluation of the motor characteristics.

Initiating Operating Sequence. If it is acceptable for the operator to start and stop the motor at the controller, the manual type of controller is permissible. Where remote control or automatic operation in response to temperature, pressure, liquid level, etc., is required, a magnetic controller must be used.

Location

THE AMBIENT TEMPERATURE, if above 40 C, and the **altitude,** if greater than 3300 ft above sea level, may affect the choice of motor. See p. 16-09. If a motor is to operate in a very moist atmosphere, special insulation or, under severe conditions, totally enclosed or enclosed and separately ventilated construction may be required. Extreme conditions of dirt or corrosive atmosphere also require totally enclosed or enclosed and separately ventilated motors. For locations where explosive dust (Class II, Group G) or gases (Class I, Group D) may be present, a corresponding type of explosionproof motor should be selected.

Outdoor application usually necessitates totally enclosed construction for protection against rain and snow. Splashproof or protected-type motors should be used only if they are low-voltage machines (below 600 volts) and are located in a mild climate. Special weather-resisting finishes are always necessary.

Underwater operation over long periods usually requires special enclosed motors, with counter air pressure to prevent entrance of water. For occasional flooding, extremely tight, totally enclosed, nonventilated motors equipped with a stuffing box at the shaft entrance may suffice. Where "hosing down" or splashing of water is involved, splashproof motors will meet all but extreme conditions, the latter requiring enclosed motors.

Noise. Installations in public buildings, such as schools, theaters, hospitals, stores, etc., and in residences, unless isolated from occupied sections, may require quiet operating motors to avoid objectionable noise. Suitable resilient mountings to prevent transmission of vibration through the building structure are often necessary. Finally, local regulations such as codes and ordinances must be considered. Some regulations demand special enclosures on motors and control equipment to reduce the hazard to operators.

ELECTRIC MOTORS

3. GENERAL CHARACTERISTICS

POWER SUPPLY. Practically all public utility power systems distribute a-c power, although d-c power is provided in the downtown areas of certain large cities. Alternating-current motors are, in general, less costly, require less maintenance, and meet the requirements of the large majority of applications. However, for certain loads d-c motors have more suitable characteristics and are used even though a-c to d-c conversion equipment is required. Direct-current motors must be designed for the proper line voltage, and a-c motors for the proper voltage, phase, and frequency.

Standard motor voltages are as follows: direct current—32, 115, 230, 550 volts; single-phase alternating current—115, 230 volts; polyphase alternating current—110, 208(60 cycles only), 220, 440, 550, 2300, 4000, 6600, 11,000, 13,200 volts. In some industrial plants, power is generated or purchased at a voltage higher than can be economically employed directly on the motors, so that a voltage transformation is necessary. If such a voltage change is economical, selection of the proper motor voltage (or voltages) depends on many factors which vary with each plant. However, it is seldom economical to select a voltage such that the horsepower ratings of the motors are outside the limits shown in Table 1. Certain types of motors are available with a *dual voltage* feature: i.e., sufficient winding terminals are provided so that the motor can be connected for either one of two voltages, such as 115 and 230 volts or 220 and 440 volts.

Table 1. Motor Horsepower Limits at Various Voltages

Single-phase Alternating Current			Polyphase Alternating Current			Direct Current		
Voltage	Horsepower		Voltage	Horsepower		Voltage	Horsepower	
	Min	Max		Min	Max		Min	Max
115	No limit	1	110	$\frac{1}{6}$	15	115	No limit	30
230	No limit	10	208–220	$\frac{1}{6}$	200	230	No limit	500
			440–550	$\frac{1}{6}$	500	550	$\frac{1}{2}$	No limit
			2300	75	No limit			
			4000	150	No limit			
			6600	400	No limit			
			11000	1000	No limit			
			13200	1000	No limit			

Frequency. In the United States a-c frequencies of 60 and 25 cycles are standard. The latter, primarily because of the limitations it imposes on the selection of motor speeds and its inferiority for lighting, has largely been superseded by the former. Frequencies of 50, 40, and 30 cycles also are in use in certain sections of the United States but are being superseded by 60 cycles. In Europe and European dependencies, 50 cycles is the general standard. In Canada, except for parts of Ontario, 60 cycles is standard.

Phase. Single-phase, three-phase, and, to a limited extent, two-phase power is distributed and used commercially in the United States. Three-phase energy is most satisfactory for power purposes and is the accepted standard. In general, single-phase motors cost more and have less satisfactory operating characteristics than three-phase machines. However, single-phase power is employed for lighting and in residential and rural districts often is the only power available. Hence, single-phase motors commonly are used on household appliances and other small equipment to be installed in such districts. Power companies place a limit on the size of motor which may be connected to single-phase lines. This limit usually falls between $^1/_4$ and $^3/_4$ hp for 110-volt circuits and between 3 and 10 hp for 220-volt circuits.

HORSEPOWER RATING. Motors usually are rated in horsepower, the rating representing their power output. Very small motors (less than $^1/_{20}$ hp) usually are rated in watts output (746 watts = 1 hp) or in millihorsepower (mhp) where 1000 mhp = 1 hp. Standard ratings have been established for the various types of motors.

Most motors are rated on a continuous basis; that is, they will carry rated load continuously. However, many types, such as crane and hoist motors, are given short time ratings such as 15-min, $^1/_2$-hr, or 1-hr ratings, indicating that they can carry their rated load for the designated period of time, after which they must be allowed to cool to room temperature. Some motors are given several different ratings, each for a different period of time. Short-time-rated motors are used on intermittent loads, the time rating being chosen to give the motor heating equivalent to that produced by the actual duty cycle of the load.

TEMPERATURE RISE. Motors are designated 40 C, 50 C, etc., to indicate the temperature rise in degrees centigrade that will not be exceeded when the motor carries rated load continuously (or for a specified time in the case of short-time-rated motors). The temperature rise refers to the windings, core, and other parts adjacent to the insulation. Some motors are given different temperature guarantees for different parts, such as armature, field, etc. Temperatures usually are determined by thermometer, although temperature detectors embedded in the winding are used on large motors. In some cases, the temperature rise of a winding is determined by measuring the change in its resistance.

Temperature rise guarantees usually are on the basis of normal conditions of ventilation, an altitude of not more than 1000 meters (3300 ft), and an ambient temperature of 40 C. Less effective dissipation of heat at higher altitudes (a result of reduced density of air) causes a higher temperature rise. It is assumed that the temperature rise as measured at altitudes below 3300 ft is 1% less than the temperature rise at a higher altitude for each 330 ft by which this altitude exceeds 3300 ft. Expressed as an equation, this becomes

$$t_h = \frac{t_s}{1.1 - (h/33{,}000)}$$

where t_h = temperature rise at altitude h, t_s = temperature rise at sea level, h = altitude, feet. Thus a motor having a temperature rise of 40 C at sea level will have at an altitude of 9900 ft a temperature rise of

$$t_h = \frac{40}{1.1 - (9900/33{,}000)} = 50 \text{ C}$$

The type of insulation has an important bearing on the allowable temperature rise. For Class A insulation (see p. 16-02) the upper temperature limit is placed at 105 C. If the insulation is allowed to reach a higher temperature, unduly rapid deterioration is expected. For Class B insulation the upper temperature limit is placed at 125 C. Class A insulation is standard for most types of motors, although Class B insulation usually can be obtained at increased cost. Since it is impractical to measure the temperature of a motor at the *hottest spot*, standard practice limits the temperature as measured to a lower value.

If the temperature is measured by thermometer, it is assumed that the thermometer reading will be 15 C below the hottest-spot temperatures for open motors and 10 C for totally enclosed or totally enclosed, fan-cooled machines. If temperature detectors are used, the differential is taken as 5 C, and with the resistance method the differential is taken as 5 C for open and totally enclosed fan-cooled machines (zero differential on totally enclosed motors.) On this basis the temperature limits and temperature rises (based on 40 C ambient) are as given in Table 2. If a motor is to operate in an ambient temperature in excess of 40 C, a motor should be chosen with a temperature rise correspondingly lower.

Many types of motors are rated on the basis of a temperature rise less than allowable for the type of insulation employed. For example, a 40 C rise by thermometer is a common rating for motors with Class A insulation, whereas in a 40 C ambient temperature a rise of 50 C is allowable. Such motors are frequently guaranteed to have a certain overload capacity, which is not available in motors rated at the maximum allowable temperature. Temperatures and temperature rises usually are given in degrees centigrade. For conversion of centigrade to Fahrenheit and of Fahrenheit to centigrade, see pp. 28-53 and 28-54.

Table 2. General Temperature Limits for Motors

	Class A Insulation, °C	Class B Insulation, °C
Measured by thermometer method		
Temperature limit, open motors	90	110
Temperature limit, totally enclosed and totally enclosed fan-cooled motors	95	115
Temperature rise (40 C ambient), open motors	50	70
Temperature rise (40 C ambient), totally enclosed and totally enclosed fan-cooled motors	55	75
Measured by temperature detectors		
Temperature limit	100	120
Temperature rise (40 C ambient)	60	80
Measured by resistance method		
Temperature limit, open and totally enclosed fan-cooled motors	100	120
Temperature limit, totally enclosed motors	105	125
Temperature rise (40 C ambient), open and totally enclosed fan-cooled motors	60	80
Temperature rise (40 C ambient), totally enclosed motors	65	85

SPEED CHARACTERISTICS. All motors may be classified according to their speed characteristics as follows: (1) constant-speed, (2) varying-speed, (3) adjustable-speed, (4) adjustable-varying-speed, and (5) multispeed.

A constant-speed motor is one in which the speed is practically constant regardless of load. A change of a few per cent in speed between no load and full load is characteristic, except with synchronous motors. Induction motors with small slip and d-c shunt motors are constant-speed machines.

A varying-speed motor is one in which speed varies with load, ordinarily decreasing as load increases. The series d-c motor and the high-slip, squirrel-cage induction motor are typical.

An adjustable-speed motor is one in which the speed can be varied gradually over a considerable range but, being unaffected by the load, remains practically constant when once adjusted. The d-c shunt-wound motor with field resistance control, designed for a considerable range of speed adjustment, is an example of this type of motor.

An adjustable-varying-speed motor is one in which the speed can be varied gradually over a considerable range, but the speed, when once adjusted to a given load, will vary in considerable degree with change in load; for example, a wound-rotor induction motor with secondary resistance control.

A multispeed motor is one which can be operated at any one of several definite speeds, each being practically independent of the load. An induction motor with a primary winding capable of various pole groupings is an example.

Operating Speeds. A characteristic of all constant-speed a-c motors is that their operating speed is equal to or slightly less than one of the *synchronous speeds* corresponding to the frequency of the power supply (see Table 3). Multispeed a-c motors operate at two or more of these speeds. Synchronous motors, as their name implies, operate at exact synchronous speed. Induction motors operate at synchronous speed under no load, but under load they operate at a slightly lower speed. The difference between synchronous speed and full-load speed is known as full-load slip; it varies between 1 and 5% of synchronous speed for constant-speed induction motors. Direct-current motors can be designed for any required speed, subject to mechanical limitations. However, for the purpose of standardization, constant-speed d-c motors usually are designed for full-load speeds approximately equal to the full-load speeds of 60-cycle induction motors.

In some cases, the speed classification of a motor depends entirely on the control used with it. For example, a wound-rotor induction motor may be constant speed, varying speed, or adjustable varying speed with no structural change in the motor whatsoever. A constant-speed d-c motor may become, with no change in the motor itself, a wide-range adjustable-speed motor by the provision of means for varying the voltage impressed on its armature.

DIRECTION OF ROTATION. The standard direction of rotation for all nonreversing motors, with the exception of polyphase induction motors, is counterclockwise as one faces the end of the machine opposite the drive. Unless otherwise specified, standard motors are designed or connected for the standard direction of rotation. In polyphase a-c motors

Table 3. Synchronous Speeds Possible at Various Frequencies

No. of Poles	60 Cycles	50 Cycles	40 Cycles	25 Cycles	No. of Poles	60 Cycles	50 Cycles	40 Cycles
2	3600	3000	2400	1500	52	138.5	115.4	92.3
4	1800	1500	1200	750	54	133.3	111.1	88.9

48	150	125	100	....	98	73.5		
50	144	120	96	....	100	72		

the terminals must be connected to the power lines in accordance with their phase rotation marking. This rule does not apply to polyphase induction motors whose terminals are not marked for any particular direction of rotation. They must be connected to the power lines, and, if the direction of rotation is wrong, two leads are reversed. Most motors can be reversed either by a change in connections or by mechanical adjustments.

EFFICIENCY. The efficiency of a motor is defined as the ratio of useful power output to the total power input. Since power input is usually given in kilowatts,

$$\text{Efficiency} = \frac{0.746 \times \text{Horsepower output}}{\text{Kilowatts input}}$$

$$\text{Kilowatts input} = \frac{0.746 \times \text{Horsepower output}}{\text{Efficiency}}$$

Motors of the same type and rating usually differ but little in efficiency. There may be considerable difference in the efficiency of motors of different types; this is particularly true of adjustable speed motors operating at reduced speeds. The efficiency of motors also varies considerably with the load and usually is highest at three-fourths or full load. At light loads the efficiency is quite low.

POWER FACTOR. The power factor of a motor is defined as the ratio of the kilowatts input to the kilovolt-amperes input where

$$\text{Kilovolt-amperes} = \frac{\text{Volts} \times \text{Amperes}}{1000} \quad \text{for single-phase motors}$$

$$= \frac{1.73 \times \text{Volts} \times \text{Amperes}}{1000} \quad \text{for three-phase motors}$$

$$= \frac{2 \times \text{Volts} \times \text{Amperes}}{1000} \quad \text{for two-phase motors}$$

Thus the kilovolt-amperes input to a motor equals kilowatts input/power factor.

Direct-current motors and certain types of a-c motors have a power factor of unity (100%); that is, kilowatts input equals kilovolt-amperes input. However, the more common types of a-c motors, such as the induction motor, have a *lagging* power factor of less than unity. For the effect of low power factor and for the means of improving it, see the *Power* Volume of Kent's *Mechanical Engineers' Handbook*, Section 16, Articles 12 and 13.

The product of the efficiency and the power factor of a motor is the *apparent efficiency*. Thus

$$\text{Kilovolt-ampere input} = \frac{\text{Kilowatts}}{\text{Power factor}} = \frac{0.746 \times \text{hp}}{E \times \text{Power factor}}$$

$$= \frac{0.746 \times \text{hp}}{E_a}$$

where E = efficiency and E_a = apparent efficiency.

FULL-LOAD CURRENT. The full-load current of a motor is the current drawn from the line when the motor is carrying full load, with rated voltage and frequency (a-c motors) applied. It may be calculated as follows, $I_{\max}$ being the full-load current.

Direct-current Motors

$$I_{\max} = \frac{746 \times \text{Horsepower}}{\text{Efficiency} \times \text{Voltage}}$$

Single-phase A-c Motors

$$I_{\max} = \frac{746 \times \text{Horsepower}}{\text{Efficiency} \times \text{Voltage} \times \text{Power factor}}$$

Three-phase A-c Motors

$$I_{\max} = \frac{746 \times \text{Horsepower}}{1.73 \times \text{Efficiency} \times \text{Voltage} \times \text{Power factor}}$$

Two-phase A-c Motors, 4-wire *

$$I_{\max} = \frac{746 \times \text{Horsepower}}{2 \times \text{Efficiency} \times \text{Voltage} \times \text{Power factor}}$$

Approximate values of full-load current for popular types and ratings of motors are given in Table 4.

TORQUES. The full-load torque of a motor is fixed by its horsepower and speed rating.

$$\text{Full-load torque in pound-feet} = 5250 \times \frac{\text{Horsepower}}{\text{Rpm}}$$

This is the basic torque of a motor. Other torques (see below) are often expressed as a percentage of full-load torque.

Other motor torques of importance are (1) starting torque, (2) pull-up torque (a-c motors), (3) breakdown torque (a-c motors), (4) pull-in torque (synchronous motors), and (5) pull-out torque (synchronous motors).

Starting torque of a motor is the torque developed at zero speed. In a-c motors it is the minimum torque for all angular positions of the rotor, with rated voltage and frequency applied to the motor.

Pull-up torque is the minimum external torque developed by the motor during the period of acceleration from rest to the speed at which breakdown torque occurs. For motors that do not have a definite breakdown torque, the pull-up torque is the minimum torque developed up to rated speed.

Rated breakdown torque of an a-c motor is the maximum torque the motor will carry, with rated voltage and frequency applied to the motor, without an abrupt drop in speed. It indicates the peak load the motor can carry without stalling or decelerating to a low speed.

Pull-in torque of a synchronous motor is the maximum constant torque under which the motor will pull its connected inertia load into synchronism, at rated voltage and frequency, when its field excitation is applied. The speed to which a motor will bring its load depends on the power required to drive it; and whether the motor can pull the load into step from this speed depends on the inertia of the revolving parts. Hence, pull-in torque cannot be determined unless the Wk^2 of the external load and the torque of the load are known.

Pull-out torque of a synchronous motor is the maximum sustained torque the motor will develop at synchronous speed for 1 min, with rated voltage applied at rated frequency and with normal excitation.

---

* Where two-phase motors are supplied from a three-wire circuit, the current in the common wire is 1.41 times the current in either other wire.

Table 4. Approximate Full-load Currents of Motors

Horsepower of Motor	Full-load Current—Amperes																			
	Direct-current Motors		Alternating-current Motors																	
			Single-phase Motors		Three-phase															
					Induction Motors								Synchronous Motors

STARTING CURRENT. It is characteristic of most motors that if full-line voltage is impressed on their terminals at start (rotor at standstill) a current considerably in excess of the normal running current will be drawn from the line. This current usually is designated *locked rotor current* and is defined as the current taken from the line with the rotor locked and with rated voltage applied (as well as frequency in the case of a-c motors).

For d-c motors, starting current must be held to certain limits (usually 150 to 300% of full load current) to prevent excessive burning of the motor commutator. This prevents starting these motors on full voltage except in the smaller sizes. Reduced-voltage starting is generally recommended for motors larger than about 1 hp, although 115- and 230-volt motors rated 1750 rpm and below may be started on full voltage in sizes up to 1 1/2 hp (shunt wound) or 5 hp (series or compound wound) with some reduction in brush and commutator life. Reduced-voltage starting is usually accomplished by means of a resistor temporarily inserted in series with the armature winding.

The full-voltage starting current of a-c motors varies over a wide range for the different types of motors and may be as high as ten times normal full-load current. Hence, reduced-voltage starting sometimes is necessary to prevent distortion of the windings and resultant failure of the insulation. However, with a few exceptions a-c motors have the windings adequately braced, and full-voltage starting is permissible so far as the motor is concerned. But, in any case, reduced-voltage starting frequently is necessary to prevent undue voltage disturbance on the power lines. The starting current, flowing through transformers, transmission lines, and feeders, may cause a drop in voltage sufficient to dim the lights supplied from the circuit or to cause other motors to stall or trip off the line.

Most power companies have established regulations governing the starting current that may be drawn by motors connected to their distribution systems.

The following regulations for single-phase motors have been adopted by some utilities and are becoming recognized as reasonable limitations:

Rule 1. Automatically controlled single-phase motorized equipment designed for general use shall be equipped with motors having locked-rotor currents at rated voltage designed not to exceed the following: (1) 20 amperes at 115 volts; (2) 25 amperes at 230 volts. A tolerance of +15% of these current values taken at 25 C is acceptable in testing any individual motor. Note: Exceptions may be made for automatically started equipment whose operating cycles will normally involve long runs with infrequent starting.

Rule 2. Manually controlled single-phase motorized equipment designed for general use shall be equipped with motors having locked-rotor currents at rated voltage designed not to exceed the following. (1) 40 amperes at 115 volts. (2) 50 amperes at 230 volts. A tolerance of +15% of these current values taken at 25 C is acceptable in testing any individual motor.

Rule 3. Single-phase motorized equipment, to be used where industrial, commercial, or other large loads or special conditions exist, may, upon approval of the electric utility, be equipped with motors having locked-rotor currents in excess of those allowed by Rule 1 and Rule 2.

For polyphase motors, the maximum starting currents as given below are allowed by some utilities. These limits generally permit full-voltage starting.

Horsepower	Amperes at 220 Volts *	Horsepower	Amperes at 220 Volts *	Horsepower	Amperes at 220 Volts *
1 or less	24 †	15	220	75	1085
1 1/2	35	20	290	100	1450
2	45	25	365	125	1815
3	60	30	435	150	2170
5	90	40	580	200	2900
7 1/2	120	50	725		
10	150	60	870		

* Current at other voltages is inversely proportional to the voltage.
† Amperes per horsepower (this rating only).

Where no power company regulation exists, the limits of motor starting current are determined by the voltage variation permissible and the drop in voltage that results from a given increase in current. To avoid any perceptible light flicker it is necessary to prevent a sudden change in voltage in excess of approximately 2% of normal voltage; but in many cases a considerably greater voltage change, particularly if it occurs at rare intervals, will not be objectionable. So far as motors are concerned, a 10 or 15% momentary drop in voltage usually is not serious, although in some special applications the resulting change in motor speed may cause difficulty. The drop in voltage caused by a given increase in current is determined by the rating and characteristics of the generating equipment and by the resistance and reactance of transformers and feeders supplying the motor.

All a-c motors rated $^1/_{20}$ hp and larger, except polyphase wound-rotor motors, now have on their name plate a "Code" letter selected from Table 5. This letter indicates the locked-rotor kilovolt-ampere per horsepower drawn by the motor on full voltage (NEMA standard).

Table 5. Code Letters for Locked-rotor Kilovolt-ampere

(NEMA Standard)

Code Letter	Kilovolt-amperes/hp	Code Letter	Kilovolt-amperes/hp	Code Letter	Kilovolt-amperes/hp
A	0 –3.15	H	6.3– 7.1	P	12.5–14.0
B	3.15–3.55	J	7.1– 8.0	R	14.0–16.0
C	3.55–4.0	K	8.0– 9.0	S	16.0–18.0
D	4.0 –4.5	L	9.0–10.0	T	18.0–20.0
E	4.5 –5.0	M	10.0–11.2	U	20.0–22.4
F	5.0 –5.6	N	11.2–12.5	V	22.4–and up
G	5.6 –6.3				

It is characteristic of most motors that if the starting current is reduced, for example, by means of a reduced voltage starter, the starting torque will also be reduced. Hence, the starting torque of the motor and the torque required by the load must be considered, as well as the starting current. A high ratio of starting torque to starting current (called *torque efficiency*) obviously is desirable when severe starting-current restrictions exist. This ratio varies over a wide range for the different types of motors and may vary with the type of control equipment employed.

MECHANICAL FORMS. In its simplest form a motor may consist simply of the stator and rotor windings with their necessary magnetic structures. Certain types of small motors often are in this form. The rotor then is mounted on a shaft of the driven machine, which also is provided with a suitable support for the stator. However, a motor usually is furnished with shaft, two bearings, and mounting feet forming part of the stator frame. The bearings usually are carried by *end shields* that bolt to each end of the frame. Very large motors often have pedestal-type bearings. In this case, a base may be provided which supports the stator and the bearing pedestals, or individual sole plates may be provided for each bearing pedestal and for each side of the stator frame.

Motors sometimes are supplied without mounting feet, being supported from the end shield on the drive end. This shield has a machined flange or face for bolting to the driven machine. This same construction may be used to support the driven machine by the motor wholly or partially. In this case the motor feet are retained.

Motors with belt drives usually have a sliding base that permits adjustment of the motor position, in a direction perpendicular to the shaft, for tightening the belt. The smaller standard two-bearing motors are suitable for belt drive. In the larger sizes, an outboard bearing is provided.

Good practice under normal operating conditions for flat belt, V-belt, gear, and chain drive on motors without outboard bearings is shown in Table 6.

Table 6. Speed Limitations—Two-bearing Motors for Flat-belt, V-belt, Gear, and Chain Drives

(NEMA Standard)

Full-load Rpm of Motor		Maximum Horsepower Rating of Motor			
Above	Including	Flat-belt Drive	V-belt Drive	Gear Drive	Chain Drive
2400	3600	20	20	..	20
1800	2400	30	40	..	40
1500	1800	40	75	5	75
1200	1500	40	75	10	75
900	1200	75	125	25	125
750	900	125	200	50	200
720	750	150	250	75	250
560	720	200	300	75	300

All motors are available in the standard horizontal-shaft construction. Most types also are obtainable in the vertical-shaft construction. In this case the motor is supported by feet or a ring base which forms part of, or is bolted to, the lower end shield. Two types of vertical motors are available. The *normal-thrust type* is designed to carry a moderate thrust load (280 to 2100 lb, depending on rating) in addition to the weight of the motor rotor and coupling. The *high-thrust type* is designed to carry substantially higher thrust loads. Certain types of vertical motors can be obtained in *hollow-shaft construction.* These are used primarily for deep-well pumping, as the hollow shaft allows the pump shaft to be brought to the top of the motor for convenient coupling to the motor shaft and for adjustment of its length.

The combination of a motor with an enclosed speed-reducing gear, built as an integral unit and designated *gear motor*, is offered by several manufacturers. The sizes available range from 1/6 to 75 hp, with output shaft speeds of approximately 13.5 to 780 rpm. An 1800 rpm motor usually is employed. Various types of gear reduction units are used, including the internal planetary with concentric output shaft, the worm and wheel type with right-angle shaft, and the straight helical gear reduction with parallel offset shaft. The gear motor has a considerably lower cost than that of a conventional motor of corresponding output-shaft speed.

The type of bearings—sleeve, ball, or roller—varies with the size and type of motor. Sleeve bearings are oil lubricated, with oil rings or waste packing to carry the oil from the reservoir to the bearing surface. Ball and roller bearings are generally grease lubricated, although oil lubrication often is employed for large, high-speed motors and for the thrust bearing of large vertical motors.

ENCLOSING AND PROTECTIVE FEATURES. A motor normally requires the circulation of air through its interior to remove the heat resulting from the motor losses. If there is no restriction to the flow of ventilating air other than that necessitated by mechanical construction, the motor is designated as *open type*. Although this type is most common and the lowest in cost, a number of other types are available, offering various degrees of enclosure.

A protected motor is one in which all ventilating openings in the frame are protected with a wire screen, expanded metal, or perforated covers, with openings not exceeding 1/2 sq in. in area and are shaped so as not to permit the passage of a rod larger than 1/2 in. in diameter. If the distance of exposed live parts from the guard is more than 4 in., openings may be 3/4 in. in diameter. This construction is designed to prevent accidental contact with rotating or live parts. Its use is confined largely to d-c motors.

A semiprotected motor is one in which some of the ventilating openings in the frame, usually those in the top half, are protected as in a protected machine, the others being left open.

A drip-proof motor is one in which the ventilating openings are so constructed that drops of liquid or solid particles falling on the machine at any angle not greater than 15 degrees from the vertical cannot enter the machine either directly or by striking and running along a horizontal or inwardly inclined surface.

A splashproof motor is one in which the ventilating openings are so constructed that drops of liquid or solid particles falling on the machine or coming towards it in a straight line at any angle not greater than 100 degrees from the vertical cannot enter the machine either directly or by striking and running along a surface.

A totally enclosed motor is one enclosed to prevent exchange of air between the inside and the outside of the case but not sufficiently enclosed to be termed airtight. It protects the motor from dirt, moisture, chemical fumes, or other harmful ingredients of the surrounding atmosphere.

A totally enclosed fan-cooled motor is a totally enclosed machine equipped for exterior cooling by means of a fan or fans integral with the machine but external to the enclosing parts. It serves the same purpose as the totally enclosed motor. The fan-cooling feature is desirable on larger motors to dissipate the heat.

An enclosed self-ventilated motor is one having openings for the admission and discharge of ventilating air, which is circulated by means integral with the machine, which is otherwise totally enclosed. The openings are so arranged that inlet and outlet ducts or pipes may be connected to them. This construction serves the same purpose as the totally enclosed type in which air free from harmful ingredients can be obtained within a reasonable distance. It also prevents heat, resulting from the motor losses, from being discharged into the motor room.

An enclosed separately ventilated motor is one having openings for the admission and discharge of the ventilating air, which is circulated by means external to and not a part of the machine, which otherwise is totally enclosed. These openings are so arranged that inlet and outlet ducts or pipes may be connected to them. This construction, rather than the enclosed self-ventilated construction, is employed on low-speed machines whose rotor fans do not develop sufficient pressure to circulate the ventilating air through the required duct length.

Both the enclosed self-ventilated and the enclosed separately ventilated machines can be provided with a closed system of ventilation; that is, the hot air discharged from the machine can be cooled and then recirculated through the machine. Cooling usually is accomplished by water circulated through surface air coolers. The closed system of ventilation generally is restricted to rather large machines.

An explosionproof motor is one in an enclosing case which is designed and constructed to withstand an explosion of a specified gas or dust that may occur within it and to prevent the ignition of the specified gas or dust surrounding the motor by sparks, flashes, or explosions that may occur within the machine casing. Such motors are designed for certain hazardous locations.

The National Electrical Code (Article 500) classifies hazardous locations as follows.

Class I. Locations in which flammable gases or vapors may be present in the air in sufficient quantities to produce explosive or ignitable mixtures. Subdivisions of this class are: Group A, atmospheres containing acetylene; Group B, atmospheres containing hydrogen or gases or vapors of equivalent hazard such as manufactured gas; Group C, atmospheres containing ethyl ether vapor; Group D, atmospheres containing gasoline, petroleum, naphtha, alcohols, acetone, lacquer solvent vapors, propane, butane, and natural gas.

Class II. Locations which are hazardous because of the presence of combustible dust. Subdivisions of this class are: Group E, atmospheres containing metal dust; Group F, atmospheres containing carbon black, coal, or coke dust; Group G, atmospheres containing grain dust.

Class III. Locations which are hazardous because of the presence of easily ignitable fibers or flyings, but in which such fibers or flyings are not likely to be in suspension in air in sufficient quantities to produce ignitable mixtures.

The code also recognizes two divisions of each class of hazardous locations, designated Division 1 and Division 2:

Class I, Division 1 locations are those in which hazardous concentrations of gas or vapor (1) exist under normal operating conditions, (2) exist frequently because of repair or maintenance operations or leakage, or (3) exist as a result of breakdown or faulty operation of the equipment which might also cause simultaneous failure of the electrical equipment.

Class I, Division 2 locations are those in which flammable gases or vapors can exist only in case of (1) accidental rupture or breakdown of the container or system in which they are normally confined, (2) a failure or abnormal operation of ventilating equipment which normally prevents hazardous concentrations of the gas or vapor, or (3) occasional communication of the gas or vapor from an adjacent Class I, Division 1 location.

Class II, Division 1 locations are those in which (1) explosive or ignitable mixtures of dust may occur under normal operating conditions, (2) such mixtures are produced in the vicinity of electrical equipment under abnormal operation or failure of equipment, or (3) dusts of an electrically conducting nature may be present.

Class II, Division 2 locations are those in which explosive or ignitable mixtures of the dust normally will not be in suspension in the air during normal operation or as a result of abnormal operation or failure of the equipment, but (1) where deposits of dust may be sufficient to interfere with the safe dissipation of heat from electrical equipment, or (2) where such deposits of dust in the vicinity of the electrical equipment might be ignited by arcs, sparks, or burning material from such equipment.

Class III, Division 1 locations are those in which easily ignitable fibers or materials producing combustible flyings are handled, manufactured, or used.

Class III, Division 2 locations are those in which ignitable fibers are stored or handled (except in process of manufacture).

For **Class I, Division 1** locations, the code specifies explosionproof motors approved for Class I locations. For **Class I, Division 2** locations, it permits either explosionproof motors or open motors with no sliding contacts, switching mechanism, or integral resistance unit (or with such devices provided with an explosionproof enclosure approved for Class I locations).

For **Class II, Division 1** locations, totally enclosed (not ventilated, pipe-ventilated, or fan-cooled) motors approved for Class II locations are specified except where dust from the production of magnesium, aluminum, or aluminum bronze powders may be present. In the latter case totally enclosed (not ventilated or fan-cooled) motors specifically approved for such locations are required. For **Class II, Division 2** locations, totally enclosed (not ventilated, pipe-ventilated, or fan-cooled) motors are specified. However, in locations where, in the judgment of the code-enforcing authority, only moderate accumulations of nonconducting, nonabrasive dust are likely to occur and where the equipment is readily accessible for routine cleaning and maintenance, self-cleaning textile motors of the squirrel-cage type or standard open-type machines without sliding contacts, switching mechanisms, or integral resistances (or else with such devices enclosed in tight metal housings without openings) may be installed. Protected or splashproof motors are not to be used.

For **Class III, Division 1** locations, totally enclosed (not ventilated, pipe-ventilated, or fan-cooled) motors are specified. However, in locations where, in the judgment of the code-enforcing authority, only moderate accumulations of lint and flyings will be likely to collect on, in, or near a motor and where the motor is readily accessible for routine cleaning and maintenance, self-cleaning textile motors of the squirrel-cage type or standard open-type machines without sliding contacts, switching mechanisms, or integral resistances (or else with such devices enclosed in tight metal housings without openings) may be used. For Class III, Division 2 locations, totally enclosed (not ventilated, pipe-ventilated, or fan-cooled) motors are specified. Protected and splashproof motors are not permitted for Class III locations.

At present no motors are available for Class I, Division 1, Groups A and B locations. Motors in sizes up to 20 hp (at 3600 rpm) are obtainable for Class I, Division 1, Group C locations and in sizes up to 500 hp (at 3600 and 1800 rpm) for Class I, Division 1, Group D locations. Motors are also available in sizes up to 200 hp (at 3600 and 1800 rpm) for Class II, Division 1, Group E locations, and in sizes up to 500 hp (at 3600 and 1800 rpm) for Class II, Division 1, Groups F and G conditions.

The Underwriters' Laboratories, Inc., established and maintained by the National Board of Fire Underwriters, offers a testing and inspection service available to manufacturers of equipment for hazardous locations. Motors that have been tested and inspected by them are provided with a label so indicating. Since most inspection authorities look to the Underwriters' Laboratories for guidance as to the suitability of equipment for hazardous locations, motors with this label generally are acceptable for the specified atmospheres anywhere in the United States.

Motors for installation in mines come under the jurisdiction of the U. S. Bureau of Mines. This body does not issue approvals covering a motor or controls but approves only a complete power-using assembly consisting of a machine, such as pump, coal cutter, conveyor, etc., combined with the motor that drives it and the complete control equipment and wiring. However, certain types of motors are available which have passed the inspection and tests of the U. S. Bureau of Mines, indicating that they are eligible for ultimate approval, without further tests, as part of a complete power-using assembly.

4. SMALL-POWER MOTORS

Small-power or fractional-horsepower motors are motors built on frames having a continuous rating of less than 1 hp (open type) at 1700 to 1800 rpm. Standard horsepower and speed ratings of small-power motors are given in Table 7. The various types in general use are as follows.

1. Single-phase motors: (*a*) shaded-pole, (*b*) split-phase, (*c*) repulsion-start induction (and repulsion-induction), (*d*) capacitor, (*e*) series-wound, and (*f*) synchronous (nonexcited).
2. Polyphase motors: (*a*) squirrel-cage induction and (*b*) synchronous (nonexcited).
3. Direct-current motors: (*a*) shunt-wound, (*b*) series-wound, and (*c*) compound-wound.
4. Universal motors (operate from either alternating current or direct current); (*a*) series-wound, and (*b*) compensated series-wound.

Table 7. Standard Horsepower and Speed Ratings of Small-power Motors

Speed in Rpm

60 Cycles		50 Cycles		25 Cycles		Direct Current	Horsepower * (max)
Synchronous	Approximate Full Load	Synchronous	Approximate Full Load	Synchronous	Approximate Full Load	Approximate Full Load	
3600	3450	3000	2850	1500	1425	3450	1
1800	1725	1500	1425			1725	3/4
1200	1140	1000	950			1140	1/2
900	850					850	1/3

* Standard horsepower ratings are 1/20, 1/12, 1/8, 1/6, 1/4, 1/3, 1/2, 3/4, and 1.

SINGLE-PHASE MOTORS are available in a variety of types, but practically all operate essentially as squirrel-cage induction motors. Since a normal single-phase induction motor does not develop any starting torque, it must be provided with an auxiliary starting-winding or phase-shifting device. The essential difference between the various types of single-phase motors lies in the type of starting-winding or phase-shifting device employed.

Shaded-pole motors have a squirrel-cage rotor winding and a concentrically wound single-phase stator winding. A portion of each stator pole is "shaded" by a single turn of heavy copper wire. Current that is out of phase with the current in the main winding is induced in the shading coil. A revolving magnetic field results, similar to that of a polyphase induction motor, and hence starting torque is developed. Motors of this type are inefficient and have rather low starting torque. However, in the small sizes they are the most economical design. They are used in ratings up to about $^1/_{25}$ hp (40 mhp) for small fans, timing devices, instruments, relays, toys, sign flashers, small motion-picture projectors, and miscellaneous control devices. They are designed for a particular direction of rotation that cannot be changed after the motor is built.

Split-phase motors have squirrel-cage rotors and two-phase stators with one of the phases wound for relatively high resistance. Since the ratios of resistance to reactance of the two phases are not equal, the currents in the phases are not of the same time phase and approach the relations of a true two-phase motor. Hence, a revolving magnetic field is produced and starting torque is developed. The high-resistance winding, because of its high losses, must be disconnected when the motor gets up to speed. The disconnecting switch usually is operated by a centrifugal mechanism on the rotor. These motors are used in ratings from $^1/_{60}$ to $^1/_3$ hp for a variety of applications whose power requirements fall within this range. Typical applications are advertising devices, fans, blowers, oil burners, kitchen appliances, machine tools, mechanical office equipment, pumps, textile and laboratory equipment, and washing and ironing machines.

Repulsion-start induction and repulsion-induction motors have a single-phase distributed winding on the stator, and a commutated winding, similar to that of a d-c machine, on the rotor. The brushes bearing on the commutator are spaced 180 electrical degrees apart and are short-circuited. Repulsion-start induction motors also have a centrifugal device which short-circuits all commutator segments when the motor has accelerated to a certain speed, converting the rotor winding to a squirrel-cage winding. Thus the motor starts as a repulsion motor but runs as an induction motor. The centrifugal device sometimes is arranged to lift the brushes of the motor as well as to short-circuit the commutator segments. Repulsion-induction motors, on the other hand, do not have any centrifugal device but instead have a squirrel-cage winding on the rotor in addition to the commutated winding. The squirrel-cage winding is placed below the commutated winding and is arranged to have a high reactance. At low motor speeds (high slip frequency) very little current flows in the squirrel-cage winding, and the motor starts essentially as a repulsion motor. When the motor reaches full speed, the frequency of the induced currents is low, so that considerable current flows in the squirrel-cage winding and the motor operates essentially as an induction motor. Repulsion-start induction or repulsion-induction motors in ratings of $^1/_6$ hp and larger have been used in such devices as pumps, compressors, machine tools, hoists, conveyors, garage and service station equipment, and woodworking machinery. However, capacitor-start motors are now more generally employed.

Capacitor motors are of three types. The *capacitor-start* motor has a squirrel-cage rotor and a main winding and an auxiliary winding on the stator. A capacitor (frequently mounted on top of the motor) is connected in series with the auxiliary winding to provide the necessary shift in time phase of the current flowing through it. Since the capacitor is intermittently rated, it must be disconnected for normal operation. Disconnection usually is accomplished by a switch operated by a centrifugal mechanism on the rotor. Capacitor-start motors are available in ratings from $^1/_6$ to 1 hp and are used on fans, pumps, compressors, coal stokers, machine tools, and in other industrial applications.

The *permanent-split* capacitor motor is similar to the capacitor-start motor except that in the permanent-split type the capacitor in series with the auxiliary winding is continuously rated and so is left in the circuit during running as well as starting. Furthermore, the capacitor is selected to give best operation at full speed (maximum efficiency and minimum noise and vibration) at a sacrifice in starting characteristics. As a result, these motors develop only 40 to 60% starting torque and can be applied only to easily started loads such as direct-connected fans and blowers. Two-speed or adjustable-speed operation of fans and blowers is often provided by controllers that in effect vary the voltage impressed on the motor. This variation raises or lowers the motor's speed-torque curve, which then intersects the blower- or fan-torque curve at different speeds.

The *two-value capacitor* motor uses different values of effective capacitance in series with the auxiliary winding during starting and running. It usually has a continuously rated capacitor that remains in the circuit during starting and running and an intermittently rated capacitor that is in the circuit during starting only. Thus this motor has a high starting torque as well as good running characteristics. However, it is seldom employed in small-power ratings.

The series-wound single-phase motor is similar in construction and principle of operation to the series-wound d-c motor. It employs a stationary field winding and a commutated rotor (armature winding), the two being connected in series. Like the series d-c motor, it is of the varying-speed type, that is, its speed increases as the load decreases. Usual full-load speeds range from 5000 to 10,000 rpm; no-load speeds range from 150 to 200% of full-load speeds. The principal advantages of series motors are their extreme compactness and light weight in relation to the power delivered. Hence, they are particularly suitable for portable devices, such as vacuum cleaners and portable tools of all types. Since they usually are built in the power-using device, they frequently are supplied as "motor parts," that is, the bare stator and rotor, without bearings or feet, the bearings and stator support being incorporated in the driven machine.

Synchronous motors in the small-power sizes usually are built as *reluctance motors.* The stators are similar to those of single-phase induction motors and may be of the shaded-pole, split-phase, or capacitor type. The rotor has a squirrel-cage winding, and the core is shaped to provide projections (salient poles) corresponding to the number of poles for which the stator is wound. The motor starts as an induction motor, but, upon reaching a speed near synchronism, it "pulls into step," owing to the effect of the salient poles, and operates at exactly synchronous speed. Unlike the large-power synchronous motor, which has a field winding on the rotor supplied with d-c excitation and which operates at unity or leading power factor with high efficiency, the reluctance motor operates at a lagging power factor and has a rather low efficiency. Hence, it is used only where exact synchronous speed is required. Typical applications include electric clocks, time switches, relays, and recording meters.

Another type of synchronous motor available in the small-power sizes is the *hysteresis motor.* Its construction is similar to that of the reluctance motor except that the rotor is perfectly cylindrical and does not have a squirrel-cage winding. Its operation depends on the permanent magnetism induced in the rotor by the magnetic field of the stator. It develops a constant torque from zero to synchronous speed. It is used principally for phonograph-turntable drive.

Also available are **synchronous inductor** motors, which are essentially inductor alternators operated as motors. They operate at low speeds such as 75 or 100 rpm and with a built-in gear reduction have output shaft speeds of 1 to 4 rpm. They are used on recording instruments, small regulating or controlling devices, and other applications that require low speeds in exact synchronism with the power-supply frequency.

POLYPHASE MOTORS. Squirrel-cage induction motors meet the requirements of practically all applications in the small-power field. They develop a high starting torque with a starting current well within the limits of polyphase systems. Their efficiencies are slightly higher than those of single-phase motors. Polyphase motors are generally available in sizes of 1/6 hp and larger at 110, 220, 440, and 550 volts.

Synchronous motors of the reluctance type are employed when exact synchronous speed is required. They are similar to the single-phase motors of this type except that no starting-winding or phase-splitting device is necessary.

High-frequency polyphase motors often are used on portable tools, textile machinery, and other applications in which the number of high-speed motors required justifies the installation of special generating or conversion equipment to supply the high-frequency power. A frequency of 180 cycles usually is employed, giving a synchronous speed (2-pole motors) of 10,800 rpm. The advantages over 60-cycle induction motors are savings in cost, size, and weight. As compared to the series motor, the high-frequency polyphase motor requires less maintenance, since it has no brushes or commutator and has a higher efficiency and better speed regulation.

DIRECT-CURRENT MOTORS of the **shunt-wound** or **compound-wound** type are used for most applications. In the smaller sizes (approximately 1/20 hp and below) shunt-wound motors are standard, whereas in the larger sizes the standard is the compound-wound. The **series-wound** motor is used where its varying-speed characteristics and high no-load speed are not objectionable. It develops a very high starting torque but has a limited output at the higher speeds.

UNIVERSAL MOTORS, which operate from either single-phase a-c or from d-c power, are all of the series-wound type; that is, they have a field winding on the stator which is connected in series with a commutated winding on the rotor. The **straight series-wound** motor has a salient pole field winding on the stator, like the ordinary d-c motor, whereas the **compensated series-wound** motor has a distributed winding arranged in slots around the periphery of the stator. The latter has the advantages of better speed regulation and commutation and higher starting torque; the former is simpler in construction and more easily ventilated. In general, the straight series-wound motor is used in sizes up to approximately 1/3 hp, and the compensated series-wound motor is employed in the larger sizes. It is not feasible to build universal motors for low-speed operation, the minimum full-load speed ranging from 1800 rpm on the larger sizes to 5000 rpm on the smaller sizes. Typical full-load speed ratings are 5000, 7500, and 10,000 rpm, with no-load speeds ranging from 12,000 to 18,000 rpm. Universal motors have a variety of applications including portable tools, office appliances, vacuum cleaners, motion-picture projectors, kitchen appliances, sewing machines, and portable equipment in general.

Operating Characteristics

TEMPERATURE RISE. The standard temperature rise of small-power motors, measured by thermometer, is 40 C for general-purpose (open-type) motors, 55 C for all totally enclosed machines, and 40 or 50 C for special-purpose (open or drip-proof) motors, depending on the application. The temperature rise of a-c motors may, at the option of the manufacturer, be determined by the resistance method, in which case a 10 C higher temperature rise is allowed.

EFFICIENCY. Typical full-load efficiencies and power factors of general-purpose 60-cycle 1725-rpm motors are shown in Fig. 2. The efficiencies of d-c motors are comparable with those of single-phase a-c motors.

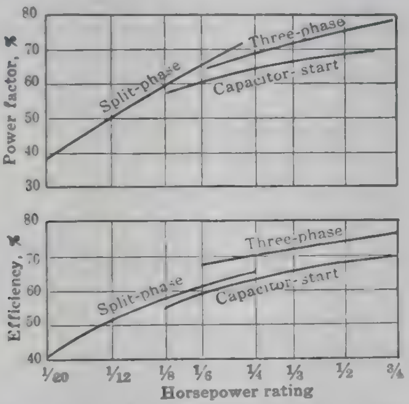

FIG. 2. Full-load efficiencies and power factors of 60-cycle 1725-rpm motors.

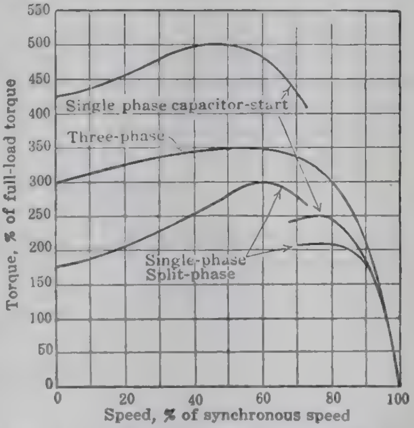

FIG. 3. Typical speed-torque curves for general-purpose small-power motors.

STARTING CURRENT. The maximum locked-rotor starting currents of single-phase motors as established by NEMA are given in Table 8. The locked-rotor currents of polyphase squirrel-cage induction motors vary between 400 and 800% of full-load current.

Table 8. Maximum Locked-rotor Starting Currents of Single-phase Small-power Motors, 60 Cycles, 900 to 3600 Rpm Inclusive *

Horsepower	1/6 and smaller	1/4	1/3	1/2	3/4
	Current in Amperes				
110 volts	20	23	31	45	61
220 volts	10	11 1/2	15 1/2	22 1/2	30 1/2

* Except the split-phase motors used on washing and ironing machines.

TORQUES. The breakdown torques for general-purpose single-phase motors standardized by NEMA are given in Table 9. The breakdown torques of special-purpose motors lie between those listed in Table 9 for the horsepower rating involved and those listed for the next smaller horsepower rating. If a higher breakdown torque is required, a motor of larger horsepower rating should be specified. The breakdown torques of squirrel-cage polyphase motors are generally equal to or greater than those standardized for single-phase motors of corresponding ratings. Typical speed-torque curves for general-purpose motors are shown in Fig. 3. Direct-current motors develop 500% or more starting torque on full voltage.

VOLTAGE VARIATION. Small-power motors should operate successfully at rated load (and rated frequency for a-c motors) at any voltage not more than 10% above or below normal, but not necessarily in accordance with the standards of performance established for operation at normal rating. An exception to this rule is the series-type

Table 9. Breakdown Torques of General-purpose Single-phase Motors

(NEMA Standard)

Synchronous Rpm	3600	3000	1800	1500	1200	1000	900

3/4	44.0	53.0	82.5	99.0			
1	58.0	69.5					

universal motor, for which the maximum allowable voltage variation is 6%. The starting currents of all types are proportional to the applied voltage, and the starting, pull-up, and breakdown torques are approximately proportional to the square of the voltage.

SERVICE FACTOR. Manufacturers of general-purpose (open-type) small-power motors generally authorize operation (at rated voltage and frequency and in an ambient temperature not exceeding 40 C) at a continuous load equal to rated load multiplied by the following service factors.

Horsepower	Service Factor
1/20, 1/12, and 1/8	1.4
1/6, 1/4, and 1/3	1.35
1/2 and 3/4	1.25
1 (3600 rpm only)	1.25

In general, slight differences in efficiencies and power factors can be expected at the loads permitted by the service factor as compared with those at rated load.

Mechanical Features

Small-power motors can be obtained as bare rotors and stators (with or without feet) for mounting directly on the driven machine. However, the usual construction consists of a stator frame provided with mounting feet and end-shield-type bearings. Motors with the drive end shield machined for bolting to the driven machine are available. Vertical motors, as well as the standard horizontal motors, are available in all types.

Sleeve bearings packed with wool yarn are standard for most open or drip-proof horizontal motors, whereas grease-lubricated ball bearings are usually furnished on enclosed or vertical motors. Ball bearings may also be employed on horizontal motors that are required to take considerable axial thrust.

Single-phase induction motors inherently produce a pulsating torque, resulting in a vibration of the motor frame which, if transmitted to the motor support, may cause an objectionable noise. Hence, such motors frequently are furnished with a resilient rather than a rigid connection between the motor frame and the motor base. This resilient connection may consist of rubber cushions, or of metal springs of sufficient flexibility to prevent or greatly reduce the transmission of vibration to the supporting structure. Some manufacturers offer motors with a resilient mounting combined with an automatic-belt-tightener base, which maintains a belt tension just sufficient to prevent slippage at all loads throughout the operating range.

Gear motors of the various electrical types are available in ratings from 1/6 to 3/4 hp with output shaft speeds of 5.7 to 520 rpm. Both concentric and right-angle shaft types are obtainable. The latter employ worm-and-wheel reduction units and have lower costs but considerably lower efficiency. The horsepower output rating of a gear motor may be much less than the rating of the motor itself, the difference depending on the type of gear and the speed ratio.

Standard motors are of open or drip-proof construction, but practically all types can be obtained in the totally enclosed construction. Most types are also available in explosionproof construction for Class I, Group D, or Class II, Group E, F, and G atmospheres. (See p. 16-19.)

WEIGHTS AND DIMENSIONS. Figure 4 gives three sets of mounting dimensions standardized by NEMA for small-power motors rated 1/20 hp and larger. Each set is identified by a frame number equal to sixteen times the *D* dimension. The frame for any particular rating is determined by the motor manufacturer. Table 10, however, shows typical frame assignments for the popular ratings of general-purpose open-type motors. Approximate weights for the various frames are also given in Table 10.

sion-induction), (2) capacitor, (3) brush-shifting repulsion, and (4) polyphase induction with phase-shifting starter.

For details of construction and principle of operation of types 1 and 2, see p. 16-21.

Repulsion-start induction and repulsion-induction motors have high starting torque and low starting current. They are used for practically all applications requiring single-phase motors. However, the simple construction, quiet operation, and low maintenance of the capacitor motor has made the latter type increasingly popular, and it is being successfully used in the majority of applications.

Capacitor motors are available in normal-starting-torque and high-starting-torque types. The former are usually capacitor-start motors for fans, blowers, centrifugal pumps, and many general-purpose applications with moderate starting-torque requirements. The high-starting-torque motors are either capacitor-start or two-value capacitor motors used in applications requiring high starting torque, such as reciprocating pumps, reciprocating compressors, and loaded conveyors.

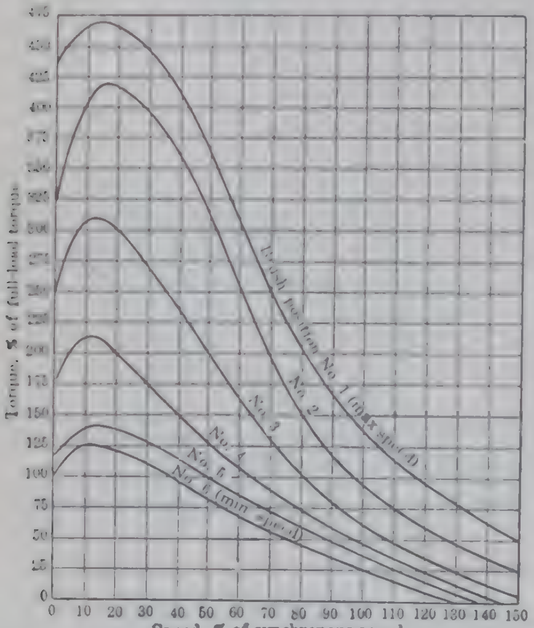

Fig. 5. Speed-torque curves of brush-shifting repulsion motor.

The brush-shifting repulsion motor is a repulsion motor provided with a mechanism for shifting the angular position of the brushes that bear on the commutator of the motor. Shifting modifies the speed-torque curves of the motor, as shown in Fig. 5. As the motor has a varying speed characteristic, the speed obtained with a given brush setting varies over a wide range, depending on the torque required by the load. Thus, to obtain the expected speed range of the motor, it is necessary to match closely the motor rating with power requirement of the load. Ratings available range from $^1/_4$ to 3 hp at 1800 to 600 rpm.

Single-phase motors are seldom used in sizes above 10 hp. Hence, none of the types described above is available in the higher ratings. When a larger single-phase motor is required, it is usual to use a polyphase induction motor with a split-phase starter of the resistance-reactance type. The horsepower output of a polyphase-induction motor operating single-phase is approximately one-half its normal rating.

Operating Characteristics

TEMPERATURE RISE. The standard temperature rise of large-power single-phase motor, measured by thermometer, is 40 C for general-purpose (open-type or drip-proof) motors, 55 C for totally enclosed and totally enclosed fan-cooled machines, and 40 or 50 C for special-purpose motors. The temperature rise may, at the option of the manufacturer, be determined by the resistance method, in which case a 10 C higher temperature rise is allowed for open and totally enclosed motors, and a 5 C higher temperature rise for totally enclosed fan-cooled machines.

For motors having a temperature rise of 40 C, manufacturers usually authorize operation (at rated voltage and frequency and in an ambient temperature not exceeding 40 C) at a continuous load equal to rated load multiplied by the following service factors.

Horsepower	Service Factor
$^1/_2$, $^3/_4$, 1	1.25
1 $^1/_2$, 2	1.20
3 and larger	1.15

EFFICIENCY. Approximate full-load efficiencies and power factors of popular ratings of normal-starting-torque capacitor motors are shown in Fig. 6.

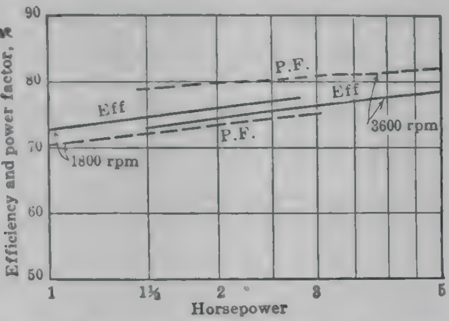

Fig. 6. Approximate full-load efficiency and power factor of normal-starting-torque capacitor motors.

TORQUES AND STARTING CURRENT. Breakdown torques of general-purpose single-phase (large-power) motors as standardized by NEMA are given in Table 12.

Table 12. Breakdown Torques of General-purpose Single-phase Motors

(NEMA Standard)

Synchronous Rpm	3600	3000	1800	1500	1200
Frequency	60	50	60	50	60
Horsepower	Torque in Pound-feet				
3/4	....	....	....	....	6.9
1	....	....	6.8	8.2	9.2
1 1/2	4.6	5.5	10.1	12.1	13.8
2	6.0	7.2	13.0	15.6	18.0
3	8.6	10.2	19.0	22.8	25.8
5	13.5	16.2	30.0	36.0	40.5
7 1/2	20.0	24.0	45.0	54.0	60
10	27.0	32.4	60.0	72.0	....

Starting torques range from approximately 160 to 200% of full-load torque for normal-torque capacitor motors and from approximately 250 to 300% for repulsion-induction, repulsion-start induction, and high-starting-torque capacitor motors. Brush-shifting repulsion motors have at least 300% starting torque and 300% breakdown torque with the brushes in the maximum-speed position. The maximum *starting currents* of large-power single-phase Design M motors as standardized by NEMA are as follows:

Horsepower Rating	Locked Rotor Current, Amperes	
	115 Volts	230 Volts
1	70	35
1 1/2	..	40
2	..	50
3	..	70
5	..	100
7 1/2	..	150
10	..	200
15	..	300
20	..	400

Design M designates motors that meet these starting currents and the breakdown torques of Table 12. Motors with higher starting currents and the same breakdown torques are designated Design L.

VOLTAGE VARIATION. Large-power, single-phase motors should operate successfully at rated load and frequency at any voltage not more than 10% above or below normal but not necessarily in accordance with the standards of performance established for operation at normal rating. The starting currents are proportional to the applied voltage, and the starting, pull-up, and breakdown torques are proportional to the square of the voltage.

Note 1. **For significance of the above letters see Fig. 7.**

Note 2. For tolerances on shaft extension diameters and keyways, see Table 17.

* Dimension *D* will never be greater than the above values, but it may be less so that shims are usually required for coupled or geared machines. When exact dimension is required, shims up to 1/32 in. may be necessary on frame sizes whose dimension *D* is 8 in. and less; on larger frames shims up to 1/16 in. may be necessary.

Mechanical Features

Large-power single-phase motors usually are furnished with feet on the stator frame and with end-shield bearings. They are also available with the drive end shield machined for bolting to the driven machine. Vertical motors, as well as standard horizontal motors, can be obtained.

Sleeve bearings, wool-yarn-packed or oil-ring-lubricated, or grease-lubricated ball bearings are standard for horizontal open or drip-proof motors. Ball bearings are standard on vertical and totally enclosed motors. All motors can be obtained with pulleys and sliding bases for two-bearing belt drive. Gear motors are available in ratings from 1 to 3 hp with output-shaft speeds of 13.5 to 780 rpm.

Fig. 7. Standard lettering used in designating dimensions of horizontal motors. See Table 13.

Standard motors are of the open or drip-proof type, but totally enclosed and explosion-proof (Class I, Group D) or dust-explosion-proof (Class II, Groups E, F, and G) motors are available.

WEIGHT AND DIMENSIONS. Mounting dimensions with corresponding frame numbers standardized by NEMA for large-power motors are shown in Table 13 and Fig. 7 (horizontal motors), Table 14 and Fig. 8 (horizontal or vertical type-C face-mounted motors), Table 15 and Fig. 9 (horizontal or vertical type-D flange-mounted motors), and

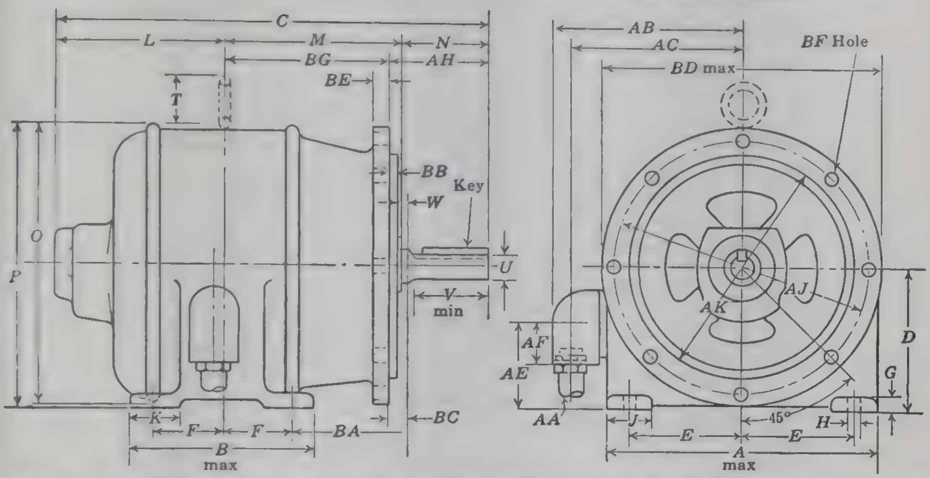
Note 1. See Fig. 8 for the meaning of the letter dimensions.

Note 2. These dimensions may also be applied to vertical motors, in which case the frame designation may have suffix letters CV or SCV.

Note 3. Dimensions *A*, *B*, *D*, *E*, *F*, and *H* do not apply to machines furnished without feet.

* Dimension *D* will never be greater than the above values. When exact dimension is required, shims up to $1/_{32}$ in. may be necessary.

† The tolerance of the *AK* dimension is +0.000, −0.003 in., for frames 203–326, inclusive, and +0.000, −0.005 in., for frames 364–445, inclusive.



Note:- Where 4 holes (*BF*) are used they are on the 45 degree from the horizontal and vertical center lines

Note 1. See Fig. 10 for meaning of letter dimensions.

Note 2. Dimensions *BD*, *AK*, *AJ*, *BB*, and *BF* (clearance hole) may also be applied to vertical solid-shaft motors.

* The tolerance for the *AK* dimension is −0.000, +0.005 in.

† Either tap size hole or clearance hole should be specified.

‡ The tolerance for the BX dimension is −0.000, +0.001 in., up to and including 1 1/2-in. diameter; −0.000, +0.0015 in., 1 1/2-in. to 2 7/16-in. diameter.

§ Horsepower at 1800 rpm.

Table 16 and Fig. 10 (vertical hollow-shaft motors, type P). The tolerances on shaft-extension diameters and keyways are given in Table 17.

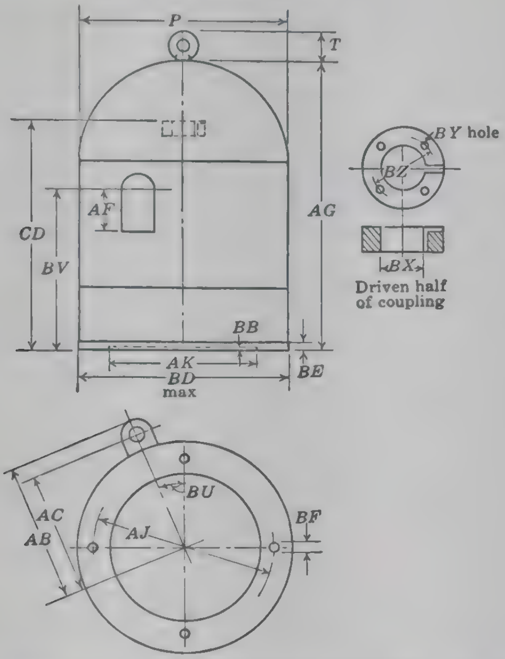

FIG. 10. Standard lettering for dimensions of vertical hollow-shaft motors, Type P. See Table 16.

Table 17. Tolerances on Shaft Extension Diameters and Keyways

(NEMA Standard)

1. Tolerance on shaft extension diameters
   - Shaft diameters, 1/4 to 1 1/2 in., inclusive: +0.000, −0.0005 in.
   - Shaft diameters, 1 5/8 to 3 3/8 inches inclusive: +0.000, −0.001 in.
2. Tolerance on width of keyways
   - Width, 3/16 to 3/4 in., inclusive: +0.000, −0.002 in.
3. Tolerance for making keyways parallel to center line of shaft
   - Shaft diameters, 3/4 to 1 1/2 in., inclusive: 0.002 in.
   - Shaft diameters, 1 5/8 to 3 3/8 in., inclusive: 0.003 in.
4. Tolerance on depth of keyways:

Shaft Diameter, inches	Key Dimensions, inches	Bottom of Keyseat to Opposite Side of Shaft, inches
5/8	3/16 × 3/16	0.517–0.502
3/4	3/16 × 3/16	0.644–0.629
1	1/4 × 1/4	0.859–0.844
1 1/8	1/4 × 1/4	0.986–0.971
1 1/4	1/4 × 1/4	1.112–1.097
1 5/8	3/8 × 3/8	1.416–1.401
1 3/4	3/8 × 3/8	1.542–1.527
1 7/8	1/2 × 1/2	1.591–1.576
2 1/8	1/2 × 1/2	1.845–1.830
2 3/8	5/8 × 5/8	2.021–2.006
2 5/8	5/8 × 5/8	2.275–2.260
2 7/8	3/4 × 3/4	2.450–2.435

The frame sizes assigned by NEMA to open, totally enclosed, and totally enclosed fan-cooled 60-cycle single-phase motors are given in Table 18. Approximate net weights are given in Table 19.

Table 18. Frame Sizes of Horizontal and Vertical 115- and 230-volt Single-phase 60-cycle Motors

Note 1. Ratings below the heavy lines are for direct connection only.

Note 2. Standard speed ratings at 50 cycles are 3000, 1500, 1000, and 750 rpm, and the standard horsepower ratings at each speed are the same as for the 60-cycle speeds of 3600, 1800, 1200, and 900 rpm, respectively.

* Applies to squirrel-cage motors only.

6. POLYPHASE INDUCTION LARGE-POWER MOTORS

Horsepower and speed ratings of large-power polyphase induction motors as standardized by NEMA are given in Table 20. Larger and lower-speed motors are also available. Motors larger than 200 hp are generally given horsepower ratings varying in steps of 50 to 500 hp, steps of 100 to 1000 hp, steps of 250 to 2500 hp, and steps of 500 to 6000 hp. The synchronous speeds available with various power-supply frequencies are given in Table 3.

TYPES of polyphase induction motors in general use are (1) squirrel-cage motors (single-speed and multispeed), (2) wound-rotor motors, and (3) adjustable-speed brush-shifting motors. Special designs of these basic types are available for specific applications including (1) crane and hoist motors, (2) elevator motors, (3) shell-type motors, (4) loom motors, and (5) screenless open textile motors.

Squirrel-cage Motors. Five classes of large-power, squirrel-cage induction motors are defined by NEMA and are designated designs A, B, C, D, and F. All designs withstand full-voltage starting but differ in their torque and/or starting-current characteristics.

Design A motors have normal starting torque (in accordance with Table 21), high breakdown torque (in excess of values shown in Table 22), high starting current (higher than values shown in Table 23), and low full-load slip (less than 5% except for motors having 10 or more poles, in which case the slip may be slightly greater than 5%). These motors are suitable for general application but often require reduced-voltage starting because of their relatively high starting current.

[†] Amperes per horsepower (this rating only).

Design B motors have normal starting torque (in accordance with Table 21), high breakdown torque (in accordance with Table 22), low starting current (in accordance with Table 23), and low full-load slip (less than 5%, except for motors having 10 or more poles, in which case the slip may be slightly greater than 5%). Design B motors are the most popular of all types since their well-balanced characteristics make them suitable for the majority of applications.

Design C motors have high starting torque (in accordance with Table 24), normal breakdown torque (in accordance with Table 25), low starting current (in accordance with Table 23), and low full-load slip (less than 5%). They are used on such devices as reciprocating compressors started under load, which require high starting torque with good running characteristics.

Design D motors have high starting torque (275% for 60- and 50-cycle, four-, six-, and eight-pole motors), low starting current (in accordance with Table 23), and high full-load slip (5% or more). No breakdown-torque values are specified, since these motors have no sharply defined breakdown point. They are used principally for drives imposing rapidly recurring peak loads (such as punch presses) and for drives involving a heavy starting duty but light or intermittent running duty. In the former application a flywheel frequently is provided to equalize the load peaks. This type of motor should not be used to drive a continuous steady load, as its efficiency is quite low.

Design F motors have low starting torque (125% for 60- and 50-cycle, four- and six-pole motors, rated 30 hp and larger), low breakdown torque (135% for motors rated 30 hp and larger), low starting current (9 amp per horsepower at 220 volts, and inversely proportional to the voltage at other voltages, for motors rated 30 hp and larger) and low full-load slip (less than 5%). These motors have a limited field of application because of their low breakdown torque. They are used occasionally when limitations of the power system make their low starting current desirable and when the driven machine has moderate starting-torque requirements and a uniform running load.

Figure 11 shows typical speed-torque curves, and Fig. 12 shows typical speed-current curves of each of the five types of squirrel-cage induction motors.

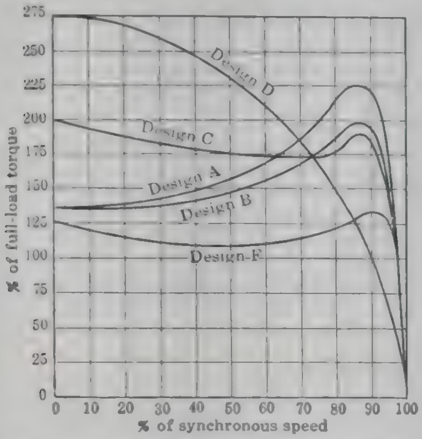

FIG. 11. Typical speed-torque curves of squirrel-cage induction motors.

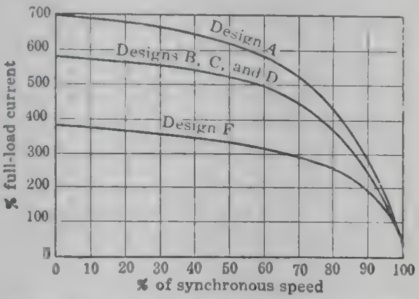

FIG. 12. Typical speed-current curves of squirrel-cage induction motors.

Multispeed squirrel-cage motors may be provided with (1) a single stator winding connected to give either one of two speeds, (2) two or more stator windings giving a corresponding number of speeds, or (3) a combination of (1) and (2). The single-winding motor is lowest in cost and has the best characteristics, but it gives only two speeds having a ratio of 2 : 1. Two or more windings must be employed where more than two speeds or other speed ratios are required.

Multispeed motors may be classified into three general types. (1) *Variable-torque motors* have horsepower ratings at each speed proportional to the square of the speed (*viz.*, 20/5 hp, 1800/900 rpm) and are used for driving centrifugal pumps, fans, and agitators. (2) *Constant-torque motors* have horsepower ratings at each speed directly proportional to the speed (*viz.*, 30/20/15/10 hp, 1800/1200/900/600 rpm) and are used for conveyors, stokers, reciprocating compressors, printing presses, and dough mixers. (3) *Constant-horsepower motors* have the same horsepower rating at all speeds (*viz.*, 5 hp, 1800/600 rpm). Typical applications are lathes, boring mills, planers, radial drills, grinders, milling machines, winches, and dragline scrapers. Multispeed squirrel-cage motors may have electrical characteristics corresponding to Classes A, B, C, or D, but in general the same characteristics are obtained at all speeds.

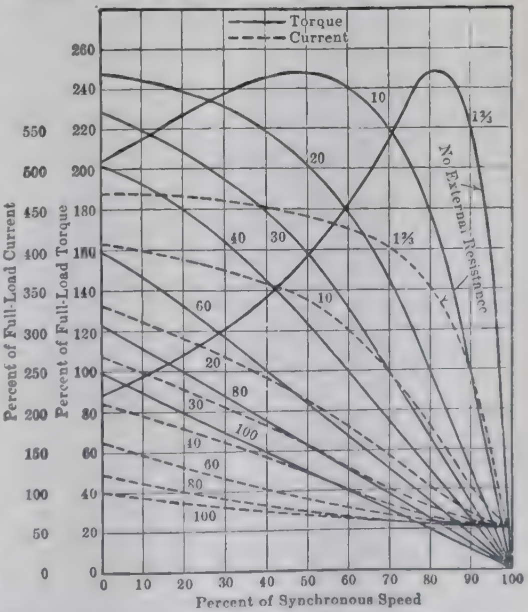

FIG. 13. Typical speed-torque and speed-current curves of wound-rotor induction motors with different external resistances in series with rotor winding.

The wound-rotor induction motor has an insulated three-phase winding on the rotor, whose terminals are connected to three slip rings. Stationary brushes bear on the latter, through which the rotor circuit is completed external to the motor. By inserting various amounts of resistance in series with the rotor winding, the torque and current characteristics of the motor can be varied as shown in Fig. 13. High starting torque thus can be obtained with very low starting current. With all resistance cut out, the characteristics of this motor are similar to those of the Class A squirrel-cage motors, but with somewhat lower efficiency. With suitable control, wound-rotor motors can operate continuously at reduced speeds down to 50% speed, but the efficiency is reduced in proportion to the speed. At reduced speeds the motor has varying speed characteristics; i.e., a change in load results in considerable change in speed. Wound-rotor motors are used occasionally where a high ratio of starting torque to starting current (high torque efficiency) is required or where severe accelerating duty is met. However, these motors are used principally on applications requiring an adjustable speed drive. They can be used economically for driving variable torque loads (centrifugal pumps, fans, etc.) at reduced speeds, but they are not economical for continuous reduced-speed operation of constant torque loads.

Multispeed wound-rotor motors also are available. When speed adjustment (by varying the secondary resistance) is required on all speeds, only two speeds can be obtained. These must have a ratio of 2 : 1. In many applications, speed adjustment is required on only one speed, in which case two-, three-, or four-speed motors, having any synchronous speeds required, can be obtained. Except on the speed which is to be adjusted, the rotor winding operates short-circuited as a squirrel-cage motor. Typical applications of multispeed wound-rotor motors include hoists for dragging and lifting service, conveyors, elevators, oil-well pumps, and rotary car dumpers.

Adjustable-speed brush-shifting motors are similar in construction to wound-rotor motors, except that the primary winding is on the rotor, the secondary winding is on the stator, and an additional adjusting winding connected to a commutator is provided on the rotor. Power is supplied to the primary winding through collector rings, and the secondary (stator) winding is connected to brushes that bear on the commutator. The brushes may be shifted around the commutator for speed adjustment. The speed range is usually 3 : 1, and popular ratings are 3 to 15 hp (at top speed), 2500/833 rpm, and 20 to 50 hp (at top speed), 1650/550 rpm. The motors are constant-torque machines, so the horsepower output is directly proportional to the speed. At a given brush setting the change in speed between no load and full-load is 5 to 10% at maximum speed and 15 to 30% at minimum speed. At the low-speed setting (normal starting position) the starting torque is about 150%, the starting current 200%, and the breakdown torque 175 to 200%. Although these motors are higher in cost than wound-rotor or multispeed squirrel-cage motors, they have the advantages of a wide speed range with an infinite number of speed points, good efficiency at all speed points, and good speed regulation. Typical applications are textile machinery, stokers, draft fans, conveyors, cement kilns, small paper machines, wire-drawing machines, laundry flat-plate ironers, traveling plate ovens, lathes, etc.

Crane and hoist motors are available in both the squirrel-cage and wound-rotor types. The squirrel-cage motors are similar to Design D or (in the smaller sizes) Design C motors, having a high starting torque and low starting current. Both the squirrel-cage and wound-rotor motors are intermittently rated (15 or 30 min for the squirrel-cage motors and 30 or 60 min for the wound-rotor motors) and are available in open construction with a 50 C temperature rise, and in totally enclosed construction with a 55 C temperature rise. All crane and hoist motors can be obtained with a shaft extension on both ends, one for the driving pinion or coupling, the other for a brake. In addition to crane and hoist duty, these motors often are used for such applications as bascule lift and swing bridges, rotary car dumpers, larry cars, coke pushers, and hydraulic gates.

Single-speed elevator motors of the squirrel-cage type are similar to Design D motors, having high starting torque and low starting current. They are available in ratings from one to 60 hp at speeds of 600 to 1800 rpm and are intermittently rated 30 min, 50 C temperature rise. They are used on low-speed freight and passenger elevators operating at a maximum car speed of about 150 ft per min.

Two-speed elevator motors also are available. They may employ a single winding giving a 2 : 1 speed ratio, or separate windings giving a speed ratio up to 6 : 1. They have a high resistance rotor winding giving Design D characteristics. These motors are available in ratings up to 100 hp with a top speed of 1200 or 900 rpm and are rated 1-hour 50 C temperature rise on the high speed. Two-speed motors are used on elevators having car speeds up to 550 ft per min. Higher-speed elevators usually require d-c driving motors.

Shell-type motors are squirrel-cage induction motors furnished with stators and rotors only, i.e., without shaft, end shields, or bearings. The stator "frame" consists of a cylindrical steel shell wrapped around the magnetic core. In some cases the steel shell is omitted and the laminations forming the magnetic core are welded together. The rotor is mounted on the shaft of the driven machine, which must also be provided with a suitable support for the stator. Shell-type motors are available in ratings up to 30 hp (at 3600 rpm) and are used for wood-working and machine tool applications such as boring machines, grinders, tapping machines, and multiple-spindle drills. They are frequently operated from a special high-frequency power supply (such as 120 or 180 cycles per sec), giving synchronous speeds up to 10,800 rpm for two-pole motors.

Loom motors are squirrel-cage motors of totally enclosed construction, exclusively for driving textile looms. The popular ratings range from 1 to 2 hp at 1800 and 1200 rpm. They have higher breakdown torque and slightly higher full-load slip than the standard Design B motors. Higher than normal Wk^2 is often provided either in the motor rotor itself or in the form of a flywheel mounted on a motor shaft extension opposite the drive end. The motor bearings are either the oil-lubricated waste-packed sleeve type or the grease-lubricated antifriction type.

Screenless open textile motors are squirrel-cage motors having electrical characteristics similar to the standard Design B machines but differing in their mechanical construction. They are open ball-bearing machines with large unobstructed passages for ventilating air which, by means of special fans on the rotor, prevents the rapid accumulation of dust or lint inside the motor. These motors have a variety of applications in textile plants, including spinning frames, cards, cleaners, draw frames, and roving frames.

Operating Characteristics

TEMPERATURE RISE. The standard temperature rise of large-power polyphase induction motors, measured by thermometer, is 40 C for general-purpose open-type motors, 50 C for splashproof motors, and 55 C for totally enclosed and totally enclosed fan-cooled machines. The temperature rise may, at the option of the manufacturer, be determined by the resistance method, in which case a 5 C higher temperature rise is allowed for totally enclosed fan-cooled motors and a 10 C higher temperature rise for other types.

For motors having a temperature rise of 40 C, manufacturers usually authorize operation (at rated voltage and frequency and in an ambient temperature not exceeding 40 C) at a continuous load equal to rated load multiplied by the following service factors.

Horsepower	Service Factor
1/2, 3/4, 1	1.25
1 1/2, 2	1.20
3 and larger	1.15

EFFICIENCY. Typical full-load efficiencies and power factors of standard Design A squirrel-cage induction motors are given in Figs. 14 and 15, respectively. Design B motors have comparable efficiencies, Design C motors slightly lower efficiencies, and Design D motors substantially lower efficiencies than Design A machines. Design B and Design C motors also have somewhat lower power factors than Design A machines. Wound-rotor motors operating at full speed have efficiencies slightly lower than those of Design A or B squirrel-cage motors, and at reduced speed their efficiency is reduced approximately in proportion to the reduction in speed.

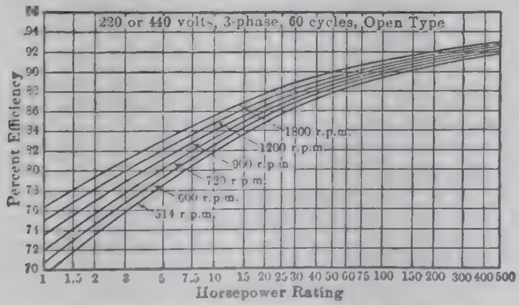

FIG. 14. Approximate full-load efficiencies of Design A squirrel-cage induction motors.

TORQUE AND STARTING CURRENT. The starting and breakdown torques and starting currents of squirrel-cage induction motors are given under the description of the various types.

As shown in Fig. 13, the starting torque and starting current of wound-rotor motors vary over a wide range, depending on the amount of external resistance in the rotor circuit. It is usual to start these motors with sufficient external resistance to give 100% torque and current at standstill, the resistance being short-circuited in steps as the motor comes-

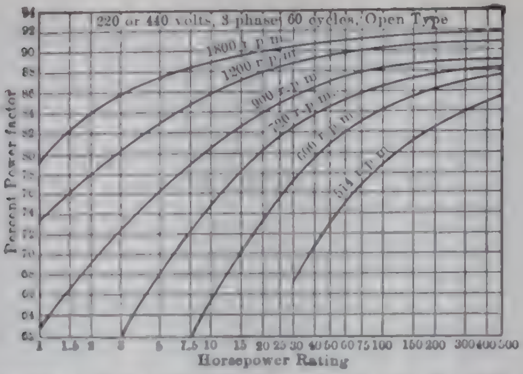

FIG. 15 Approximate full-load power factors of Design A squirrel-cage induction motors.

up to speed. The minimum breakdown torque for wound-rotor motors is 200% of full-load torque.

VOLTAGE VARIATION. All polyphase induction motors should operate successfully at rated load and frequency at any voltage not more than 10% above or below normal, but not necessarily in accordance with the standards of performance established for operation at normal rating. The starting currents are approximately proportional to the applied voltage, and the starting and breakdown torques are approximately proportional to the square of the voltage.

Mechanical Features

Large-power polyphase induction motors usually are furnished with feet on the stator frame and with end-shield-type bearings, although pedestal-type bearings, with or without base, may be used in sizes above 1 hp per rpm. The smaller motors also can be obtained with a machined face on the drive end shield or with a flange for bolting to the driven machine.

Vertical motors with either solid or hollow shafts are available. The solid-shaft motors are usually furnished with a type P base (Fig. 10) or a D flange base (Fig. 9), but the smaller sizes can be obtained with a face-type base (Fig. 8). Hollow-shaft motors generally have a type P base. Horsepower and speed ratings of vertical hollow-shaft motors standardized by NEMA are given in Table 33.

Open and drip-proof horizontal motors are generally furnished with ball bearings in sizes up to and including frame 326. In the larger sizes both sleeve- and ball-bearing motors are available, but the sleeve-bearing machines generally are slightly less expensive. Furthermore, ball bearings are not usually recommended in motor sizes above 150 hp at 3600 rpm, 250 hp at 1800 rpm, 350 hp at 1200 rpm, and 400 hp at lower speeds. Splashproof motors generally have ball bearings, as have totally enclosed and totally enclosed fan-cooled motors in sizes up to 60 hp at 3600 rpm, and 300 or 350 hp at lower speeds. Vertical motors are generally provided with ball or roller bearings except in rather large sizes, which employ plate-type thrust bearings and sleeve guide bearings.

Motor ratings suitable for flat-belt, multiple-V-belt, chain, and gear drives with two bearings are indicated in Table 6. Larger ratings require an extended base and shaft with an outboard bearing. Motors for belt or chain drive are usually furnished with a sliding base or slide rails for belt adjustment.

Gear motors are available in ratings up to 50 hp with output-shaft speeds of 13.5 to 780 rpm. High-speed (1800 rpm at 60 cycles) motors are usually employed.

Standard motors are of open or drip-proof construction, but splashproof, totally enclosed, totally enclosed fan-cooled, and explosionproof motors (Class I, Group D, or Class II, Groups E, F, and G) are also available. Totally enclosed motors are available in sizes up to 15 hp (at 1800 to 900 rpm), and totally enclosed fan-cooled motors are available in sizes ranging from 250 hp at 600 rpm to 500 hp at 1800 and 3600 rpm.

WEIGHTS AND DIMENSIONS. Frame numbers assigned to the various types of continuously rated squirrel-cage and wound-rotor motors are given in Tables 26 to 32 inclusive. Standardized mounting dimensions corresponding to the various frame numbers are given in Tables 13, 14, and 15. Approximate net weights are given in Table 34.

* Low-speed motor only.

TYPES in general use are as follows. (1) High-speed motors: (*a*) general-purpose and (*b*) large high-speed. (2) Low-speed motors. (3) Special high-torque motors.

High-speed motors operate at speeds of 500 rpm or higher. The *general-purpose* group includes those rated 200 hp or less, with speed ratings of 500 to 1800 rpm, inclusive. The *large high-speed* group includes motors rated 250 hp or more, and all two-pole ratings. (See Table 36.) The general-purpose group has somewhat higher torques, but otherwise both groups have similar characteristics. High-speed synchronous motors have somewhat the same applications as general-purpose squirrel-cage induction motors, but their use is confined largely to ratings of 50 hp or above. Except in the large sizes, the synchronous motors are more costly than the induction motors, but their high efficiency and unity or leading power factor frequently justify their use. Typical applications include pumps, motor-generator sets, fans, blowers, reciprocating and centrifugal compressors, rubber mills, and line shafts.

Low-speed motors operate at speeds of 450 rpm or below. In general, these motors have lower costs than corresponding ratings of induction motors, as well as higher efficiencies and unity or leading power factor. Typical applications include reciprocating compressors; reciprocating, centrifugal, and screw-type pumps; Jordan engines; ball mills; metal rolling mills; electroplating generators; and line shafts.

High-torque motors. Synchronous motors can be obtained with sufficient starting torque for any application and with moderate starting current. To meet the requirements of high starting torque with very low starting current, several special types of synchronous motors are available.

The *synchronous induction* motor is essentially a wound-rotor induction motor which starts in the normal manner, but after it is up to speed d-c excitation is applied to the rotor winding. This causes the motor to pull into step and operate as a synchronous motor. Thus the high starting torque with low starting current of the wound-rotor induction motor is obtained. Disadvantages of this type of motor are that its efficiency is somewhat lower than for other types of synchronous motors, and a high-current, low-voltage exciter is required for excitation.

Synchronous motors with *phase-wound* amortisseur windings are also available. These have the usual salient-pole field, but the amortisseur or starting winding, instead of being

of the squirrel-cage type, is insulated, phase-wound, and brought out to collector rings through which the circuit may be completed external to the motor. Some motors are built with a revolving armature and a stationary field, eliminating the necessity for collector rings for the field or amortisseur winding, but requiring collector rings for the a-c armature winding. In any case the motor is started with a high resistance in the amortisseur winding circuit, which is short-circuited in steps as the motor comes up to speed. Thus high starting torque with relatively low starting current is obtained.

These special types of synchronous motors are considerably more costly than the conventional type and are justified only in particular applications involving severe starting duty and low starting current.

Operating Characteristics

POWER FACTOR. Standard power-factor ratings of synchronous motors are unity and 0.8 leading, but motors rated at leading power factors down to 0.2 are available. The unity-power-factor machines are least costly and have the highest efficiency, but the leading-power-factor machines often are justified when additional leading kilovolt-amperes are required.

TEMPERATURE RISE. The temperature rise of standard open-type unity-power-factor high-speed synchronous motors is 40 C, measured by thermometer, for the armature winding, and 50 C, measured by resistance, for the field winding; for leading-power-factor high-speed motors it is 40 C, by thermometer, for the armature winding, and 60 C, by resistance, for the field winding. Splashproof motors are rated 50 C rise, by thermometer, for the armature winding, and 60 C rise, by resistance, for the field winding. The temperature rise of standard open-type unity- and 0.8-power-factor low-speed synchronous motors is 50 C, by thermometer, for the armature winding, and 60 C, by resistance, for the field winding.

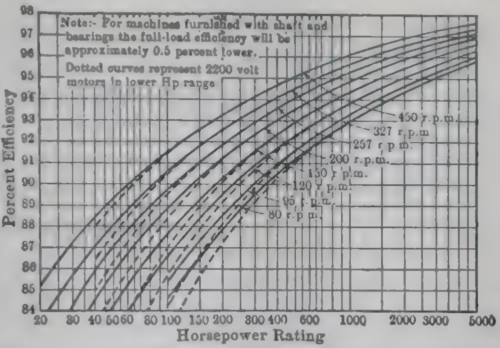

FIG. 16. Approximate full-load efficiency of low-speed synchronous motors.

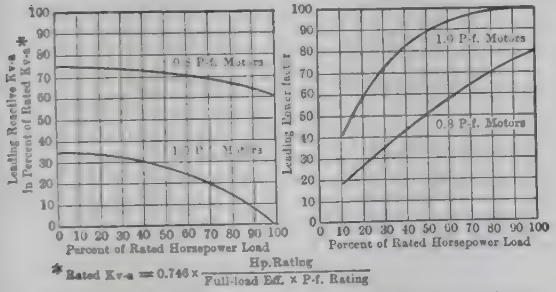
High-speed synchronous motors rated 40 C usually are given a service factor of 1.15; i.e., they may be operated at 1.15 times the rated load without injurious heating.

EFFICIENCY. Typical full-load efficiencies of unity-power-factor high-speed motors are given in Table 36, and of low-speed synchronous motors in Fig. 16. Efficiencies for machines without bearings do not include windage or friction losses. Motors rated 0.8 power factor have efficiencies ranging from 0.5 to 4% lower than for unity power-factor machines.

A synchronous motor operating at full load with rated excitation delivers *leading reactive kilovolt-amperes* to the power system. The value is determined by

$$\text{Kilovolt-amperes} = \frac{0.746 \times \text{Horsepower rating}}{\text{Efficiency} \times \text{Power factor}} \sqrt{1 - (\text{Power factor})^2}$$

When the motor operates at partial loads with rated excitation maintained, the power factor becomes more leading, and more leading kilovolt-amperes are supplied to the system. (See Fig. 17.)



$$* \text{Rated Kv-a} = 0.746 \times \frac{\text{Hp. Rating}}{\text{Full-load Eff.} \times \text{P-f. Rating}}$$

FIG. 17. Power-factor relations of synchronous motors.

TORQUE. Minimum values of starting, pull-in, and pull-out torques for general-purpose large high-speed and low-speed synchronous motors are given in Table 37. The pull-in torque of a synchronous motor varies with the flywheel effect (Wk^2) of its connected load; the higher the Wk^2, the lower the load which the motor is capable of pulling into synchronism. The values of pull-in torque given in Table 37 are based on loads having a normal Wk^2. However, motors with considerably higher starting pull-in and pull-out torques can be obtained, though usually at increased cost.

Table 37. Minimum Starting, Pull-in and Pull-out Torques of Standard Synchronous Motors

		Low-speed Motors					
		40	30	150	40	30	200

* Based on normal load Wk^2.

STARTING CURRENT. Full-voltage starting currents range from 500 to 800% for high-speed motors, and from 250 to 500% for low-speed motors.

VOLTAGE VARIATION. All synchronous motors should operate successfully at rated load and frequency at any voltage not more than 10% above or below normal, but not necessarily in accordance with the standards of performance established for operation at normal rating. Their starting currents and pull-out torques are approximately proportional to the applied voltage, their starting and pull-in torques are approximately proportional to the square of the voltage. Their pull-out torques also are approximately proportional to the excitation current.

Mechanical Features

High-speed synchronous motors usually are furnished with feet on the stator frame and end-shield-type bearings. Pedestal-type bearings, with or without base, may be used in sizes above 1 hp per rpm. A direct-connected exciter often is supplied. This is overhung

on an extension of the motor shaft on the collector-ring end (opposite the drive end). The exciter frame is bolted to the corresponding end shield or is supported from the base of pedestal-bearing machines.

Low-speed synchronous motors commonly are supplied without base, shaft, or bearings, the rotor being mounted directly on the shaft of the driven machine. In this case, a completely split-rotor spider, or split hub spider, may be furnished to facilitate assembly at the installation. Foundation caps usually are provided for support of the stator frame. A shaft, pedestal-type bearings, and base or sole plates are provided if a self-contained unit is required.

Direct-connected exciters seldom are used with low-speed synchronous motors, since higher-speed belt- or motor-driven exciters are more economical.

Sleeve bearings, oil-ring-lubricated, are standard for most horizontal synchronous motors, although grease-lubricated ball bearings can be obtained at increased cost. Vertical motors in the smaller sizes usually are furnished with ball bearings, and in the larger sizes with oil-lubricated plate-type bearings.

The horsepower limits for two-bearing belt drives are essentially the same as for induction motors (Table 6). Pulleys and sliding bases are available. Vertical synchronous motors, as well as the standard horizontal machines, can be obtained.

In addition to the open motors, dripproof, splashproof, totally enclosed fan-cooled, enclosed self-ventilated, and enclosed separately ventilated motors are available.

WEIGHTS AND DIMENSIONS. Approximate overall dimensions and net weights of high-speed synchronous motors are given in Table 38 and Fig. 18. Low-speed synchronous motors generally are specially designed for the particular application, with resultant wide variation in weights and dimensions for each rating.

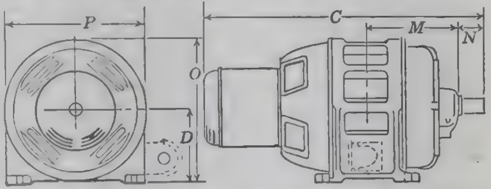

FIG. 18. Dimensions of high-speed synchronous motors. See Table 38.

8. DIRECT-CURRENT LARGE-POWER MOTORS

The following types of large-power d-c motors are in general use: (1) general-purpose constant-speed, (2) adjustable-speed, (3) large d-c, (4) crane and hoist, (5) mill-type, (6) metal rolling-mill, (7) elevator, and (8) low-speed engine-type.

General-purpose Motors. Standard horsepower and speed ratings for general-purpose constant-speed motors are given in Table 39. These motors are available with shunt-, series-, or compound-wound field windings. The shunt-wound motors have the lowest speed regulation (change in speed with change in load), are lowest in cost, and have the widest range of application. The compound-wound motors, which have somewhat higher speed regulation, are used on loads requiring high starting torque and on those subject to torque pulsation. Series-wound motors have very high speed regulation and should not be employed with belt drives or on any load in which the torque might drop below 15% of full-load torque, since a dangerously high speed would be developed. Series motors are suitable for loads requiring a very high starting torque or severe accelerating duty and where high-speed regulation is advantageous or of no consequence.

Shunt-wound constant-speed motors, having a full-load speed of 1750 rpm or below, usually can be operated at some increase in speed, without increase in horsepower, by inserting a resistance in series with the field winding. The maximum increase in speed permissible varies from about 10% for the higher speed ratings to 100% for the lower speed ratings. Speed variation by shunt field control generally is not advisable on compound-wound motors, since, with a weakened field, the motor characteristics approach those of a series motor and high speed regulation results.

Adjustable-speed Motors. These motors are shunt-wound machines designed particularly for adjustable-speed operation by varying the strength of the shunt field. Standard horsepower and minimum (basic) speed ratings and the maximum speed for each rating as standardized by NEMA are given in Table 40. As indicated, three different horsepower ratings may be given to adjustable-speed d-c motors: (1) a standard continuous horsepower rating over entire speed range, with a temperature rise of 50 C from basic speed to 150% of basic speed, and a temperature rise of 40 C from 150% of basic speed to the maximum speed; (2) a standard intermittent horsepower rating over the entire speed range, with a temperature rise of 50 C in 1 hr; (3) a *tapered rating* consisting of a certain standard horsepower from basic speed to 150% of basic speed, the next larger standard horsepower at three times basic speed and higher, and a horsepower varying along a straight line from the lower value to the upper value as the speed varies from 150% of basic speed to three times basic speed. The temperature rise is 50 C continuous from basic speed to 150% of basic speed, and 40 C continuous from 150% of basic speed to maximum speed.

In general, a motor rated in accordance with (1) will have the same cost as a motor of the next larger horsepower rated in accordance with (2), and the same cost as a tapered

rating motor whose lower horsepower is the same. Adjustable-speed d-c motors are used most extensively on machine tools.

Large d-c motors have the following standard horsepower ratings: 250, 300, 350, 400, 500, 600, 700, 800, 900, 1000, then in steps of 250 hp up to 2500 hp, and then in steps of 500 hp up to 6000 hp. Standard speed ratings in rpm are: 1150, 850, 690, 575, 500, 450, 400, 350, 300, 250, 225, 200, 175, 150, 125, 110, 100, 90, 80, 70, 65, 60, 55, and 50. The motors may be constant speed or adjustable speed (constant horsepower). The maximum speed range varies from about 5 : 1 for the smaller low-speed ratings to 1.5 : 1 for the larger high-speed ratings. Typical applications include pumps, fans, paper machines, rubber mills, and certain marine applications.

Crane and hoist motors are series- or compound-wound totally enclosed or semi-enclosed heavy-duty machines specially designed for crane and hoist service. The totally enclosed motors are usually given a 15- or 30-min rating with a 55 C temperature rise, and the semi-enclosed machines are given a 1-hr or a continuous rating with a 55 C temperature rise. The motors are available in ratings up to about 165 hp, with speed ranging from 425 to 1450 rpm. Shaft extensions at both ends, for brake and drive, respectively, and pinion, gear, and reduced-speed axle mounted integrally with the motor are available. Although higher in cost than standard motors, their compactness, rugged mechanical construction, and low-inertia armature justify their use on cranes, hoists, and similar loads involving intermittent service and severe reversing duty.

Mill motors are heavy-duty machines designed particularly for such services as steel-mill auxiliaries, oil-well drilling rigs, power shovels, cranes, bridges, hoists, and dredges. The basic motor is series-wound, totally enclosed, intermittently rated as shown in Table 41. Ratings from 7 1/2 to 200 hp are available with mounting dimensions standardized by the AISE. In addition to the series-wound motors, compound-wound and shunt-wound (constant- and adjustable-speed) motors are available, as are enclosed motors rated 30 min, protected self-ventilated motors rated 1 hr, and protected self-ventilated and force-ventilated motors with continuous ratings. In general, the horsepower and speed ratings for such motors differ from those of the basic motors. All motors have Class B insulation, roller or double-row ball bearings, and shaft extensions on both ends. A pinion, gear, and reduced-speed axle with sleeve or roller bearings also can be obtained. Rugged mechanical construction, low-inertia armatures, compactness, and accessibility of all parts are features of these motors.

Table 41. Standard Horsepower and Speed Ratings of Mill-type D-c Motors

(Series-wound, totally enclosed, 1 hr, 75 C temperature rise)

Horsepower	5	7 1/2	10	15	25	35	50	75	100	150	200	250	350
Full-load, rpm	900	800	725	650	575	525	500	475	460	450	410	375	375

Metal rolling-mill motors are heavy-duty machines designed particularly for metal rolling-mill drive. Standard horsepower and speed ratings are given in Table 42. The motors are usually arranged for adjustable-speed operation, the maximum speed varying from basic speed for the larger higher-speed ratings, to five times basic speed for the smaller lower-speed ratings. The motors normally are furnished with a base and pedestal-type bearings.

Table 42. Standard Horsepower and Speed Ratings of Adjustable-speed Metal Rolling-mill D-c Motors

Standard Basic Speed Ratings, rpm

1150, 850, 690, 575, 500, 450, 400, 350, 300, 250, 225, 200, 175, 150, 125, 110, 100, 90, 80, 70, 65, 60, 55, 50

Standard Horsepower Ratings

Horsepower	Basic Speeds, rpm	Horsepower	Basic Speeds, rpm	Horsepower	Basic Speeds, rpm
250	100 to 1150	800	60 to 850	2250	50 to 350
300	100 to 1150	900	55 to 850	2500	50 to 350
350	100 to 1150	1000	50 to 850	3000	50 to 300
400	100 to 1150	1250	50 to 575	3500	50 to 250
500	90 to 1150	1500	50 to 500	4000	50 to 225
600	80 to 850	1750	50 to 500	4500	50 to 200
700	70 to 850	2000	50 to 400	5000	50 to 175

Geared elevator hoisting machines employ high-speed motors similar to the general-purpose motors. They usually are adjustable-speed machines with shunt field control or variable armature voltage control. Gearless elevators require a special low-speed driving motor. The hoisting drum is mounted on the motor shaft between the two bearings. A brake wheel for a solenoid brake usually is cast integrally with the drum. Heavy shafts and large bearings are provided. The motors are of the adjustable-speed type with armature voltage control.

Low-speed engine-type d-c motors are available in ratings from 100 to 250 hp at speeds of 150 to 327 rpm. The standard speeds are the same as for low-speed 60-cycle synchronous motors (Table 35). The motors are compound-wound and are furnished without base, shaft, or bearings. They are used to drive low-speed machines, such as reciprocating compressors, the rotor being mounted on the shaft of the driven machine.

Operating Characteristics

TEMPERATURE RISE of standard general-purpose motors is 40 C, measured by thermometer for open motors, 50 C for semi-enclosed, drip-proof, and splashproof machines, and 55 C for totally enclosed and totally enclosed fan-cooled machines. Open motors rated 40 C usually are given a service factor of 1.15; that is, the manufacturers guarantee successful operation at 1.15 times rated load without injurious heating. Direct-current motors generally are capable of delivering 50% overload in torque momentarily, without temperature guarantee.

EFFICIENCY. Typical approximate full-load efficiencies of general-purpose constant-speed shunt-wound open-type motors are given in Fig. 19.

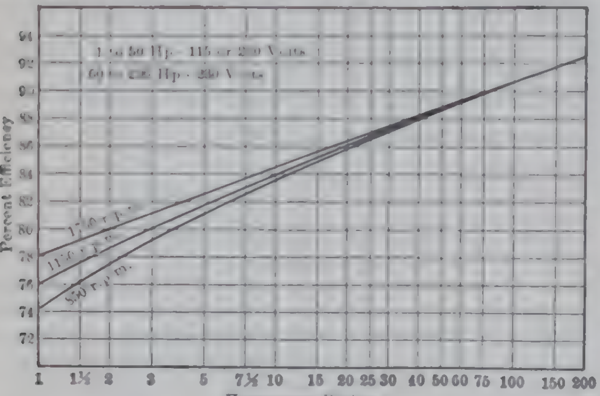

FIG. 19. Approximate full-load efficiency of general-purpose constant-speed, shunt-wound direct-current motors, open type.

TORQUE. With full voltage on the shunt field (if provided) and with the armature current limited to full-load current, the starting torque of any type of d-c motor is 100% of full-load torque. For shunt-wound motors the starting torque varies directly with the armature current; for series-wound motors it varies approximately as the square of the armature current; for compound-wound motors the variation lies between these two limits, depending on the ratio of shunt and series windings. The armature current, in turn, is determined by the amount of resistance inserted in series with this winding at start. Standard starters usually limit the current to from 125 to 200% of full-load current.

SPEED REGULATION from full load to no load, hot, based on full-load speed should not exceed the following:

Constant-speed motors, shunt-wound: 5 hp and smaller, 12%; 7 1/2 to 200 hp, inclusive, 10%; 250 hp and larger, 6%; compound-wound, constant-speed motors, 25%.

Adjustable-speed motors, shunt-wound: 2 to 5 hp, inclusive, 22%; 7 1/2 to 200 hp, inclusive, 15%; 250 hp and larger, at maximum speed, 4%; at basic speed, 6 to 15%.

At normal operating temperature, rated load, and voltage, the variation above or below rated speed should not exceed the following:

Constant-speed motors, shunt- or compound-wound, 7 1/2 hp at 1150 rpm or smaller, 7 1/2%; larger than 7 1/2 hp, at 1150 rpm, 5%.

Adjustable-speed motors, shunt-wound, 5 hp, 650 rpm (minimum speed) or smaller, 7 1/2%; larger than 5 hp, 650 rpm, 5%.

The variation in speed from full load, cold, to full load, hot, should not exceed 10%, based on full-load speed for open motors, and 15% for enclosed motors.

VOLTAGE VARIATION. All d-c motors should operate successfully at normal rated load at any voltage not more than 10% above or below normal, but not necessarily in accordance with the standards of performance established for operation at normal rated voltage. In general, with a given load, an increase in voltage results in an increase in speed and vice versa.

Any shunt-wound motor may be operated as an adjustable-speed machine by maintaining constant voltage on the shunt field while varying the voltage on the armature. The speed will be approximately proportional to the armature voltage. The basic speed of such a machine is the maximum speed (full voltage on the armature). At reduced speeds, the horsepower is reduced approximately in proportion to the speed. Thus *variable voltage control* gives constant-torque characteristics, as contrasted with speed variation by field control which gives essentially constant-horsepower characteristics. If the source of variable voltage direct current is such that the voltage is essentially independent of the current drawn, the motor is truly an adjustable-speed machine; i.e., its speed when once adjusted to a given value remains essentially constant, regardless of the load. A d-c generator, driven at constant speed with voltage variation by field control, meets this requirement and commonly is used. On the other hand, if the applied armature voltage varies appreciably with the current drawn, as it would if a variable resistance were used to reduce the voltage, the drive would be of the adjustable-varying-speed type; i.e., the speed would vary appreciably with the load.

Mechanical Features

Large-power d-c motors in sizes up to about 200 hp usually have feet on the stator frame and end-shield-type bearings. In the larger sizes, a base with pedestal-type bearings usually is supplied. Vertical motors, as well as the standard horizontal motors, can be obtained.

Sleeve bearings, oil-ring-lubricated, are standard for most horizontal machines. Ball bearings are standard on the totally enclosed, the splashproof, and the smaller vertical motors. They can be obtained on all motors at increased cost. Ball bearings usually are grease-lubricated.

Motors that can be belted with two bearings are indicated in Table 6. Sliding bases and pulleys are available. Larger ratings require an extended base and shaft with outboard bearing. Slide rails usually are supplied for belt adjustment.

Gear motors are generally available in sizes up to 7 1/2 hp with output-shaft speeds of 13.5 to 780 rpm. High-speed (1750 rpm) motors are usually employed.

In addition to the standard open-type motors, protected, semi-protected, drip-proof, splashproof, totally enclosed, totally enclosed fan-cooled, and explosionproof (Class I, Group D, and Class II, Groups E, F, and G) motors are available.

WEIGHTS AND DIMENSIONS. Frame numbers assigned to general-purpose constand-speed d-c motors are given in Table 43. Approximate net weights are given in Table 44.

9. MOTOR APPLICATIONS

The types of motors commonly selected for various applications are given in Table 45. The items listed in the table are those of general application for which conditions are well standardized. It is not possible to list the unusual conditions under which individual motors operate. Since many factors affecting the choice of motor vary with each installation, the recommendations given should be considered typical and not necessarily applicable to every case. Manufacturers of motors should be consulted with reference to the selection of the proper motor for unusual or nonstandard conditions.

Valves	Cp or Rp-In	Sq-In, Design C	Sr

* As = adjustable speed. Bs = brush shifting. Ch = crane and hoist. Cp = capacitor. Cs = constant speed. Cw = compound wound. Et = engine type. Gp = general purpose. Hs = high speed. In = induction. Lm = loom motor. Ls = low speed. Ms = multispeed. Rp = repulsion. Sh = shunt wound. Shp = shaded pole. Sot = screenless open textile. Sp = split phase. Sq = squirrel cage. Sr = series wound. Syn = synchronous. Us = single speed. V = reversible. Wr = wound rotor.

ELECTRIC MOTOR CONTROL

10. GENERAL CONSIDERATIONS

FUNCTIONS. The basic function of all motor control is to provide a means for making and breaking the connections between the motor windings and the power lines, thereby starting and stopping the motor. Practically all controllers also provide overload protection to the motor. As will be described, many other functions are provided by certain types of control.

CLASSIFICATION. Motor controllers may be classified as (1) full-voltage controllers or (2) reduced-voltage controllers. The former connect the motor directly to the power lines, that is, provide full voltage at the motor terminals during the starting period, as well as for running. The latter connect the motor to a voltage-reducing device during the starting period, and, after the motor has come up to speed, transfer the connections to the power lines. Autotransformers commonly are used to obtain the reduced voltage in a-c motor starters, although resistors and reactors frequently are employed. Resistors always are used for this purpose in d-c motor starters. Full-voltage controllers are the simplest and least expensive, but reduced-voltage controllers often are required to limit the current drawn from the power lines at start.

Motor controllers also may be classified according to the degree of automatic operation. On this basis, there are three standard types: (1) manual controllers, (2) magnetic controllers, and (3) semimagnetic controllers. In type 1 controllers, all connections to the motor are made by hand-operated switches. In type 2, the switches are electrically operated. To start the motor it is only necessary to close a pilot circuit by means of a push button, thermostat, or similar device that may be located at some distance from the controller. Reduced-voltage magnetic controllers have a relay that automatically effects the transfer from starting to running connections. In type 3 controllers, part of the starting operation is performed by hand-operated switches and the remainder by electrically operated devices.

LINE SWITCHES on low-voltage controllers (600 volts and below) usually are of the *air-break* type, i.e., the circuit is broken in air. Both air-break and oil-immersed switches are employed for the higher voltages, with the former becoming increasingly popular. Oil-immersed switches are also used in special low-voltage controllers in which the complete controller is oil-immersed. These are suitable outdoors or in corrosive atmospheres. Electromagnets, either the solenoid or clapper type, usually serve to close electrically operated switches, although motor-operated mechanisms sometimes are used on circuit breakers.

OVERLOAD PROTECTION. **Thermal-type overload relays** usually are employed. The most common form consists of a heater element that carries line current (or a current proportional to line current, obtained through a current transformer) mounted adjacent to a bimetallic strip. An overload on the motor causes an increase in line current, which increases the temperature of the heater element. The heat radiated to the bimetallic strip causes it to deflect and open a contact that disconnects the motor from the line. The time required for the relay to trip varies inversely with the magnitude of the overload, as does the length of time the motor can operate without injurious heating. With proper design, the relay will follow closely the heating characteristics of the motor. It thus adequately protects the motor and yet will not take it off the line unnecessarily (see Fig. 20). After the relay has tripped, it must be allowed to cool before it can be reset and the motor restarted. This time lapse also allows the motor to cool.

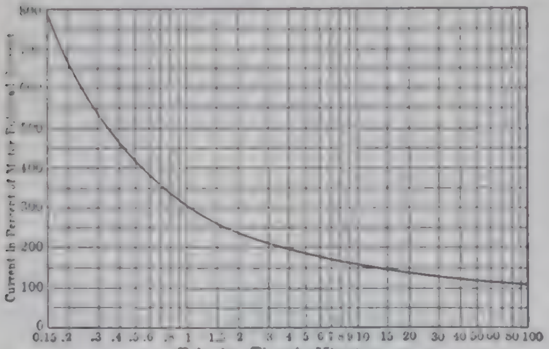

FIG. 20. Tripping characteristics of typical temperature-overload relay.

Another form of thermal overload relay, used on small motor starters, is the *solder-film* type. In this, the tripping mechanism normally is held to a stationary element by a thin film of solder. The heater that carries line current will, on an overload of sufficient duration, melt the solder film, thus releasing the tripping mechanism. After tripping the solder cools and solidifies, allowing the tripping mechanism to be reset.

Nonthermal overload relays also are used. They incorporate a time-delay feature, as an oil or air dashpot, to vary the tripping time with the magnitude of the overload. A disadvantage of this type is that when once tripped the relay can be reset immediately, and the motor started before it has had time to cool off.

Fuses. Ordinary fuses do not, in general, give satisfactory overload protection. Their time lag is so short that they usually must be oversize to prevent tripping on the starting current of the motor or on high overloads of short duration. As a result they do not give adequate protection against moderate overloads of long duration.

Relay Resets. Most overload relays are of the "hand-reset" type; that is, after tripping they must be reset manually before the motor can be restarted. In a few applications, particularly those in which the motor starts and stops automatically (for example, in response to a thermostat), it may be desirable to use an automatically reset overload relay that resets itself after a time delay of sufficient duration to permit the motor to cool. Relays of this type are available for small motors. They frequently are mounted on the motor itself and, in fractional-horsepower single-phase motors, may be designed to open directly the power circuit to the motor.

Two overload relay elements placed in different phases normally are used with three-phase and two-phase motors, whereas a single element is used with single-phase and d-c motors.

UNDERVOLTAGE PROTECTION AND RELEASE. Most controllers are so arranged that on failure of line voltage the circuit to the motor is opened. Manual starters for small motors are an exception. If the line switch is held in the closed position by a magnet energized from the line, this feature is obtained automatically. If the line switch is held closed by a mechanical latch, an *undervoltage device* must be provided, which is energized from the line and, when de-energized, operates to trip the latch. If the control is so arranged that on return of voltage the line switch recloses, *undervoltage release* is obtained. On the other hand if the line switch does not reclose on return of voltage, *undervoltage protection* is obtained. The latter is more common. The former should be used only when no hazard is involved in the motor's starting unexpectedly after a voltage failure.

In many cases, voltage failures are of very short duration, viz., 1 $^1/_2$ sec or less. Thus it is often desirable to provide control that will restart the motor if the voltage failure does not last over a certain predetermined time, but that will disconnect it permanently if the voltage failure is of longer duration. Control so arranged provides *time-delay undervoltage protection.* If the line switch is held closed by a magnet energized from the line, a time-delay push-button station generally is used. This is so arranged that its contacts are held closed for a definite time (1 to 4 sec) after a failure of voltage but can be opened instantaneously by the *stop* button. When the line switch is held closed by a mechanical latch, an undervoltage tripping mechanism incorporating a time delay in its action must be provided.

SHORT-CIRCUIT PROTECTION. The current that flows through a controller, due to a short circuit on the motor side, depends upon the characteristics of the power system to which the equipment is connected and may be a great many times the maximum current flow under normal conditions. The controller should be capable of interrupting the short-circuit current or safely withstanding this current until it is interrupted by some other device such as fuses or a circuit breaker in the circuit between the controller and the power source. With low-voltage controllers, fuses or air-circuit breakers in the branch circuit to the controller are usually provided to interrupt the short-circuit current. With high-voltage controllers, special "current-limiting" fuses are often used in a combination starter. These fuses limit the short-circuit current by interrupting it before it has built up to its peak value and thus prevent damage to the contactor and other parts of the controller. Both low- and high-voltage controllers employing a high-interrupting-capacity contactor or circuit breaker are also available.

ENCLOSURES. Open-type controllers (no enclosing case) are used where they are under competent supervision and are installed where accessible only to authorized persons. All switches and devices whose voltage rating is in excess of 600 volts should be mounted on the back of the panel or suitably enclosed to prevent accidental contact.

Controllers for small motors almost always are enclosed; enclosures can be obtained for all sizes. A number of different types of enclosure are available. The standard *general-purpose enclosure* is designed primarily to prevent accidental contact; it also protects against dust and light indirect splashing, but it is not dust-tight. It usually is of sheet-metal construction. The *driptight enclosure* is similar to the general-purpose type with the addition of drip shields or their equivalent. It is used where condensation may be severe, as in cooling rooms and laundries.

Weather-resisting enclosures are of cast construction or of suitably rigid sheet metal, with proper protection against weather hazards, as rain and sleet. They are installed on outdoor applications, as on docks, canal locks, and construction work, and also in subways and tunnels. A *watertight enclosure* is so designed that a stream of water from a hose (not less than 1 in. in diameter) under a head of 35 ft can be played on the case from a distance of 10 ft for several minutes without leakage. It is suitable for outdoor applications and for dairies, breweries, and similar locations. *Submersible enclosures* are so designed that they may be submerged in water, as in quarries, mines, and manholes. *Dust-tight enclosures* are provided with gaskets or their equivalent to exclude dust and are used in such situations as often occur in steel and cement mills.

Controllers for Class I, Group D, hazardous locations (see p. 16-19) may be of the air-break or oil-immersed type. Air-break controllers depend on the strength of the enclosing case to resist the force of an internal explosion, and on long, close fits at all joints to cool the flame and prevent ignition of the surrounding atmosphere. In oil-immersed controllers, all contacts and connections are immersed in oil to prevent ignition of the surrounding atmosphere. This construction is preferable where the control is placed in a corrosive atmosphere. Controllers for Class II, Group G, conditions, and others designed to meet the requirements of the U. S. Bureau of Mines, also are available.

Combination magnetic starters consist of a full-voltage magnetic starter combined with a manually operated motor circuit switch (fused or unfused), or a circuit breaker, mounted in a single enclosing case. Thus, means are provided for disconnecting the motor and starter, and (with fuses or circuit breaker) protection is supplied against short circuits in the starter, motor, or wiring on the motor side of the switch. General-purpose, dust-tight and watertight enclosing cases are available. Oil-immersed switches suitable for corrosive atmospheres, or for Class I, Group D hazardous locations, also can be obtained.

Frequently, a saving in space and in installation expense is obtained with a combination magnetic starter instead of the two separate devices. Combination starters are available in ratings up to 100 hp at 220 volts, and 200 hp at 440 or 550 volts.

LOCATION. In general, controllers should be placed within sight of the motor they control. If this is not feasible, the controller or disconnecting device should be provided with means for locking it in the open position, or a manually operated switch, which will prevent restarting, should be placed within sight of the motor. This switch may be located in the pilot circuit of the controller.

11. CONTROL FOR SINGLE-PHASE MOTORS

TYPES. The following types of control for single-phase motors are in common use: (1) manual full-voltage, (2) magnetic full-voltage, (3) manual reduced-voltage, (4) adjustable-speed (for capacitor motors), and (5) reversing.

Manual full-voltage controllers are available in sizes up to 1 $^1/_2$ hp at 110 volts, 3 hp at 220 volts, and 5 hp at 440 and 550 volts. They consist of a single- or double-pole line switch and an overload relay, usually of the solder-film type, mounted on a compound base. They may be obtained open, or enclosed in a sheet-metal case. Explosionproof enclosures with air-break switches for Class I, Group D conditions also are available. The smaller controllers ($^3/_4$ hp and below) usually are arranged so they can be flush mounted, using a sectional switch box and tumbler-switch flush plate. Small single-phase motors ($^3/_4$ hp and below) can be obtained with a tumbler switch mounted on the motor to serve as a starter. These do not provide overload protection and should not be used where the switch may be called upon to interrupt the stalled current of the motor.

Manual, full-voltage controllers are the lowest in cost of all types and are used where full-voltage starting is acceptable and where remote control or automatic operation is not required. They do not provide undervoltage protection.

Magnetic full-voltage controllers are available in sizes up to 7 $^1/_2$ hp at 110 volts, 15 hp at 220 volts, and 25 hp at 440 and 550 volts. They consist of a magnetic contactor mounted on a compound base. A thermal-type overload relay usually is provided in sizes above 1 hp at 110 volts and 1 $^1/_2$ hp at 220 volts. Various types of enclosures are available, including general-purpose, dust-tight, watertight, and explosionproof for Class I, Group D conditions (both air-break and oil-immersed). In the smaller sizes, enclosing cases with start-stop push buttons in the cover can be obtained. Otherwise, a separately mounted push-button station, either instantaneous or time-delay type, must be used. These are also available with general-purpose, dust-tight, watertight, and explosionproof enclosures. Frequently a thermostat, pressure switch, or similar device is used for pilot-circuit control, providing undervoltage release.

Since full-voltage starting of single-phase motors generally is acceptable and remote or automatic control often is necessary, full-voltage magnetic starters have a wide field of application covering practically all types of drive.

Manual reduced-voltage controllers consist of a rheostat, which at start is inserted in series with the motor winding, thus limiting the current drawn from the line. As the motor comes up to speed, the operating handle of the rheostat is turned, which short-circuits the resistance step by step until the motor is on full voltage. A magnet, whose coil is energized from the line voltage, holds the operating handle in the running position. If voltage fails, the handle is released and the motor is disconnected from the line. Overload protection ordinarily is not included. Manual reduced-voltage starters usually are provided with a general-purpose enclosing case. They are used only when the full-voltage starting current of the motor would cause objectionable voltage disturbance. Since the starting torque of the motor is reduced in proportion to the square of the current drawn, it is apparent that a reduction in the current drawn from the line will be obtained only if the load does not require the full-voltage torque of the motor to start.

Adjustable-speed controllers for capacitor fan motors usually consist of ring-wound autotransformers with a movable tap by which the voltage impressed on the motor is varied, thus changing the motor speed. They are available in sizes up to $^3/_4$ hp.

Reversing controllers usually are of the full-voltage type. Manually operated drum or cam switches are available for this service, in sizes up to 1 $^1/_2$ hp at 110 volts, 3 hp at 220 volts, and 5 hp at 440 or 550 volts. These controllers do not provide overload or undervoltage protection. Magnetic reversing switches are obtainable in sizes up to 7 $^1/_2$

hp at 110 volts, 15 hp at 220 volts, and 25 hp at 440 and 550 volts. They consist of two magnetic contactors, mechanically interlocked to prevent closing of both at the same time. Both overload and undervoltage protection are provided. A three-button push-button station is required. Enclosing cases of the general-purpose type usually are supplied, although watertight and dust-tight enclosing cases also are available.

12. CONTROL FOR POLYPHASE INDUCTION MOTORS

TYPES. The following types of control for polyphase induction motors are in general use:

Squirrel-cage induction motors: (1) manual full-voltage, (2) magnetic full-voltage, (3) manual reduced-voltage (autotransformer type), (4) manual reduced-voltage (resistor type), (5) magnetic reduced-voltage (autotransformer type), (6) magnetic reduced-voltage (resistor type), (7) multispeed, and (8) reversing.

Wound-rotor induction motors: (1) manual primary and secondary, (2) magnetic primary, manual secondary, and (3) magnetic primary and secondary.

Squirrel-cage Motors

Manual full-voltage controllers of the air-break type for squirrel-cage induction motors are available in sizes up to 5 hp at 220 volts, and 7 $^1/_2$ hp at 440 and 550 volts. They consist of a manually operated switch and a two-element, thermal-type, overload relay, mounted in an enclosing case. Undervoltage protection is not provided.

Standard enclosing cases are of the general-purpose type, but dust-tight and watertight enclosure and enclosures suitable for Class I, Group D or Class II, Group G hazardous locations are available.

Magnetic full-voltage controllers are obtainable in all sizes. They are the most popular of all types. The common form consists of a magnetic contactor combined with a thermal-type overload relay mounted in an enclosing case. Air-break-type contactors are standard for voltages of 600 and below, but completely oil-immersed starters are available for corrosive atmospheres. For higher voltages both air-break and oil-immersed contactors are employed. A start-stop push-button station or similar device for closing and opening the pilot circuit also is required. Enclosing cases of the general-purpose, dust-tight, and watertight type are available. Explosionproof controllers for Class I, Group D conditions can be obtained in both the air-break and oil-immersed types. In the smaller sizes of low-voltage controllers, enclosing cases of the general-purpose, dust-tight, watertight, and explosionproof (air-break) type with start-stop push buttons mounted in the cover are available.

Combination magnetic starters are also available. In the higher voltages (2300 and 4160 volts) these starters consist of magnetic contactors and disconnecting-type current-limiting fuses, making them suitable for installations on power systems having a high short-circuit current. Controllers employing a circuit breaker for the line switch and having whatever current-interrupting capacity is required can also be obtained.

Manual reduced-voltage autotransformer controllers are available in sizes up to 300 hp at 220 volts, 700 hp at 440 or 550 volts, and 900 hp at 2000 to 5000 volts. They consist of an autotransformer with two or three sets of low-voltage taps and an oil-immersed double-throw manually operated switch. In starting, the operating handle is first moved in one direction connecting the motor to a set of reduced-voltage taps of the autotransformer and held in that position until the motor has come up to speed, then the handle is moved quickly in the opposite direction to connect the motor directly to the line. The operating handle usually is interlocked mechanically, so that it must be moved to the start position before it can be moved to the run position. Overload and undervoltage (instantaneous or time-delay) protection are provided. General-purpose enclosing cases are standard, but dust-tight cases also are available.

The manual autotransformer starters are, in general, the least costly of the various reduced-voltage types. They are used whenever manual control is acceptable, and a reduction is desirable in the current drawn, or torque developed, by the motor on full voltage.

The current drawn from the line is reduced in proportion to the square of the voltage tap. For example, if the motor is connected to the 80% voltage tap, the current drawn from the line will be approximately 64% of the full-voltage starting current of the motor. Since the torque developed by an induction motor also varies as the square of the voltage impressed on its terminals, the ratio of starting torque to starting current (*torque efficiency*) remains essentially the same as with full-voltage starting.

Manual reduced-voltage resistor controllers are available in ratings up to 15 hp at 220 volts, and 20 hp at 440 and 550 volts. They consist of a rotating drum switch and a resistor. Rotation of the drum switch connects the motor to the line through the entire resistor and then successively short-circuits sections of the resistor until the motor is connected directly to the line. Neither overload nor undervoltage protection are provided. These controllers are used largely for motors driving machine tools, hoists, small cranes, and similar devices requiring manual control of the torque delivered by the motor.

Magnetic reduced-voltage autotransformer controllers are available in all sizes. These controllers are similar to the manual autotransformer type, except that, in place of the manual switch, magnetic contactors and a relay, usually of the definite-time type, effect the transfer from reduced voltage to full voltage. Overload and undervoltage protection are provided. The latter may be obtained by a time-delay push-button station, or, in the case of contactors held in by a mechanical latch, a time-delay undervoltage tripping mechanism may be provided on the contactor itself. General-purpose and dust-tight enclosing cases are available. Completely oil-immersed controllers, both low-voltage and high-voltage, can be obtained for corrosive atmospheres.

Magnetic reduced-voltage controllers of the autotransformer or reactor type with current-limiting fuses are available in sizes up to 700 hp at 2300 volts, and 1250 hp at 4160 volts, for use where high current-interrupting capacity is required.

Magnetic reduced-voltage resistor controllers are obtainable in sizes up to 250 hp at 220 volts and 500 hp at 440 and 550 volts. They are similar to the autotransformer type except that a resistor, inserted in series with the motor windings at start, serves, instead of an autotransformer, to obtain the reduction in voltage. Since the resistor is simply short-circuited as the motor comes up to speed, the circuit to the motor is not opened during the starting period. Hence this type of controller is well adapted for use where the starting current limitations do not limit the total current that can be drawn, provided the current is built up in steps of a certain magnitude without opening the circuit between steps. Frequently, a number of accelerating contactors and relays are provided. These short-circuit the starting resistor in steps in order to limit the current increment on each step to the required value.

Unlike autotransformer starting, resistor starting results in a reduction in the starting torque efficiency, since the current drawn from the line is reduced in proportion to the voltage impressed on the motor and the starting torque is reduced in proportion to the square of the voltage.

Multispeed Controllers. Controllers for multispeed induction motors are available in both the manual and magnetic type. The manual type consists of a rotating drum switch and can be obtained in sizes up to 10 hp at 220, 440, and 550 volts for two-, three-, or four-speed motors. It does not provide overload or undervoltage protection. The magnetic type is available in all sizes. It is made up of magnetic contactors, one for each speed, suitably interlocked so that only one can be closed at a time. An overload relay for each speed is required to give complete overload protection. With a momentary-contact push-button station (one start button for each speed) undervoltage protection is provided. Controllers for two-speed motors can be provided with a *compelling relay*, which makes it necessary to start the motor on low speed only, or with a *sequence relay* that starts the motor on low speed regardless of which start button is pressed but that automatically transfers to high speed after a definite time delay, when the high-speed button is pressed. General-purpose enclosing cases normally are supplied.

A multispeed motor also may be controlled by a manually operated switch, which makes the proper connections for each speed, plus a line switch, manual or magnetic, for making and breaking the circuit to the motor. Since the manual switch is operated only when the line switch is open, it does not have to open or close on current, and a knife switch or inexpensive type of drum switch can be employed. Undervoltage protection may be provided in the line switch. In place of the line switch, a reduced-voltage controller may be employed to reduce the starting current.

Reversing controllers may be of the manual or magnetic type. The manual type consists of drum switches and is available in sizes up to 10 hp at 220, 440, or 550 volts. It does not provide overload or undervoltage protection. The magnetic type is made up of two magnetic contactors and is available in all sizes. The contactors usually are interlocked mechanically, so that both cannot be closed at the same time. Overload and undervoltage protection normally are provided. A three-button push-button station is required. General-purpose, watertight, and dust-tight enclosing cases are available. Reversing control also may be provided by a manually operated drum switch (in sizes up to 75 hp at 220 volts, and 150 hp at 440 or 550 volts) or a knife switch, which serves to reverse the connections to the motor, plus a manual or magnetic full-voltage or reduced-voltage controller for making and breaking the circuit to the motor.

Wound-rotor Motors

Wound-rotor induction motors require control for both the primary (stator) winding and the secondary (rotor) winding.

The primary control connects the primary winding to the source of power. It is similar to squirrel-cage motor control of the full-voltage type and may be either manual or magnetic.

The secondary control varies the resistance of the secondary circuit of the motor, i.e., provides a high resistance at the start and decreases it as the motor comes up to speed. It consists of a resistor connected across the slip rings of the motor and manual or magnetic switches for short-circuiting the resistor in steps as the motor comes up to speed. The resistor usually is designed to limit, to the full-load values, the current drawn and the torque developed by the motor. As the resistor is short-circuited the starting torque increases, up to the maximum torque of the motor, with a corresponding increase in current. If a portion of the resistor is allowed to remain in the circuit, the motor will operate at reduced speed. In this case the resistor must be designed for continuous duty. Before closing the primary switch, the full value of secondary resistance should be inserted in the circuit.

Manual primary and secondary control may consist of a single drum switch with contacts for closing the primary circuit as well as for short-circuiting the secondary resistor. A separate resistor must be provided. These drum switches are available in sizes up to 100 hp at 220 volts, and 200 hp at 440 or 550 volts. They frequently are arranged to reverse the motor as well by changing the primary connections. Manual primary and secondary control, in sizes up to 500 hp, may be supplied by a face-plate-type rheostat or drum switch, with resistor for secondary control, combined with a manual full-voltage controller for primary control. If an oil-circuit breaker is used for the latter, it generally can be provided with a *magnetic lock*, which prevents the breaker from being closed unless the secondary controller is in the starting position, i.e., unless all the resistance is in the circuit.

Magnetic primary and manual secondary control is similar to the type just described except that a magnetic controller is used for primary control. The secondary controller usually is so arranged that moving the operating handle to the first position closes the control circuit to the primary switch, causing it to close. Thus complete control of the motor is obtained at the secondary controller.

Magnetic primary and secondary control employs magnetic contactors for the primary switch and either a motor-operated drum switch or magnetic contactors for short-circuiting the secondary resistor. Definite-time relays or current relays which operate in response to the drop in secondary current as the motor comes up to speed are used to close the several secondary contactors in proper sequence. Overload and undervoltage protection normally are provided. The controllers may be obtained in the open type or with general-purpose enclosures. Although more costly than other types, these controllers give complete control from a remotely mounted push button. They also can be obtained with an extra contactor for automatic reversing.

13. CONTROL FOR DIRECT-CURRENT MOTORS

TYPES. Direct-current motor controllers of the following types are in general use: (1) Manual controllers: (*a*) full voltage, constant-speed, (*b*) reduced-voltage, constant-speed, (*c*) reduced-voltage, adjustable-speed, by field control, (*d*) reduced-voltage, adjustable-speed, by armature control, (*e*) reduced-voltage, adjustable-speed, by armature and field control, (*f*) drum controllers. (2) Magnetic controllers: (*a*) full-voltage, constant-speed, (*b*) reduced-voltage, constant-speed, and (*c*) reduced-voltage, adjustable-speed, by field control.

Manual full-voltage constant-speed controllers are available in ratings up to 1 hp at 115 and 230 volts. They consist of a single-pole or double-pole switch and a single-element thermal-type overload relay mounted in a general-purpose or explosionproof (Class I, Group D, conditions) enclosing case. These simple and low-cost controllers are applicable to small motors in which full-voltage starting and manual control are acceptable.

Manual reduced-voltage constant-speed controllers are available in ratings up to 75 hp at 115 volts, and 150 hp at 230 and 550 volts. They consist essentially of a dial-type switch and a resistor. As the operating handle is turned, the switch first connects the motor armature to the line through the entire resistor and then short-circuits the resistor in steps until the motor is on full voltage. Full voltage is applied to the field winding throughout. A retaining magnet, which holds the operating arm in the running position, releases the arm and disconnects the motor on failure of voltage. Controllers rated 550 volts and the larger 115- and 230 volt controllers usually have a magnetic contactor connected in series with the circuit to the motor. This interrupts the current so that no current is broken on the dial-switch contacts. The controllers are generally furnished with general-purpose enclosing cases.

Manual reduced-voltage adjustable-speed controllers with field-control speed adjustment are available in ratings up to 30 hp at 115 volts and 50 hp at 230 volts. They are similar to the constant-speed controllers described above, with the addition of a resistor, inserted in series with the field winding, and means for short-circuiting the resistor in steps, thereby varying the field current and the speed of the motor. The dial switch has an extra set of segments or buttons by means of which the field current is varied. The control is so arranged that all the resistance in the field circuit must be short-circuited before the motor can be started.

Armature-control speed adjustment controllers are available in ratings up to 15 hp at 115 volts, 25 hp at 230 volts, and 5 hp at 550 volts. They are similar to the constant-speed controllers, except that they have a continuously rated armature resistor and the operating handle of the dial switch can be set in various positions to leave a certain portion of the resistor in the circuit. Thus the voltage impressed on the armature of the motor can be varied, with consequent variation in speed. Speed reduction down to 50% of full speed is standard. With this type of control the speed of the motor varies considerably with the load. It cannot be used where close speed regulation is required.

Armature and field-control speed adjustment controllers are available in ratings up to 15 hp at 115 volts, 25 hp at 230 volts, and 5 hp at 550 volts. They consist of a combination of the two types described above. A variable armature resistance, sufficient to give 50% speed reduction, and a variable field resistance to give 25% speed increase are standard.

Manual drum controllers of the full-voltage type are available in ratings up to 3 hp at 115 and 230 volts. The reduced-voltage type can be obtained in ratings up to 35 hp at 115 volts, 65 hp at 230 volts, and 100 hp at 550 volts. Both types can be obtained for reversing as well as for nonreversing duty. The reduced-voltage type also is suitable for adjustable-speed operation either by field or by armature control. If field control is provided, the field resistor usually is mounted on the side of the controller, and the drum switch has segments for short-circuiting the resistor in steps as the operating handle is turned. The armature resistor generally is mounted separately.

Drum controllers arranged to provide *dynamic braking* also can be obtained. The motor is connected as a generator and a resistor is connected across the armature so that, when the motor is driven by an overhauling load, power is delivered to the resistor, which holds back the load.

Since drum controllers do not furnish overload or undervoltage protection, a *protective panel*, consisting of a magnetic contactor and a temperature overload relay mounted in an enclosing case, often is used. The contactor will open on failure of voltage, disconnecting the motor, after which the drum controller must be returned to the off position in order to reclose the contactor. In the event of injurious overload, the relay will open the contactor. An open-close push-button station is recommended. This may be located at any convenient place and provides an additional means for stopping the motor. Drum controllers are employed with motors driving machine tools, cranes, hoists, and similar devices, when a convenient and compact manual controller is required.

Magnetic full-voltage constant-speed controllers, both reversing and nonreversing, are available in ratings up to 1½ hp at 115 volts, and 2 hp at 230 volts. They consist of a magnetic contactor and a single-element overload relay. Enclosing cases can be obtained in general-purpose, watertight, dust-tight, and explosionproof (Class I, Group D) construction.

Magnetic reduced-voltage constant-speed controllers are available in all ratings. They consist of a starting resistor, two or more magnetic contactors, and relays, usually of the definite-time type, for closing the contactors in proper sequence to short-circuit the resistor as the motor comes up to speed. Some types have accelerating contactors, incorporating a time-delay feature. These eliminate the necessity for a separate relay. A single-element temperature-overload relay and a general-purpose enclosing case usually are provided. Controllers arranged for dynamic braking with or without reversing features also are available.

Magnetic reduced-voltage adjustable-speed controllers with speed adjustment by *field control* are available in all sizes. They are similar to the type described above, with the addition of a field rheostat for varying the field current, and hence the speed, of the motor. A *field-accelerating relay* often is added, which prevents high armature current when the motor accelerates rapidly from basic speed (full field) to a higher speed (weak field). A "field-protective" relay may be installed to protect the motor from excessive speed if the field circuit is opened accidentally.

14. CONTROL FOR SYNCHRONOUS MOTORS

The control for the armature (primary) winding of a synchronous motor is similar to that provided for a squirrel-cage induction motor. (See p. 16-61.) It may be of the full-voltage or reduced-voltage type, either manual or magnetic. In addition, control for the field winding must be provided. This control usually is of the magnetic type, so that after the primary control has connected the armature winding to the a-c power lines direct current automatically is applied to the field winding when the motor has accelerated to the proper speed, i.e., 95 to 98% of synchronous speed. When the magnetic field control is combined with magnetic primary control the complete controller is designated *magnetic*, and when combined with manual primary control it is designated *semimagnetic*.

A field contactor and *field-application relay* are required to apply field excitation automatically. The latter may be of the definite-time type or it may be of a speed-responsive type operating from changes in the electrical characteristics of the motor as it approaches synchronous speed. In addition, a *discharge resistor* must be connected across the field winding during the starting period in order to limit the voltage induced in that winding. The discharge-resistor circuit is opened when field excitation is applied, either by normally closed contacts on the field contactor or by a separate field discharge contactor actuated by the field-application relay. Synchronous motor controllers also include a *field-removal relay*, which operates automatically to open the field contactor and remove excitation whenever the motor pulls out of synchronism. The latter condition may occur as a result of a high overload or a drop in line voltage. By removing field excitation, after the load or voltage returns to normal, the motor may be able to re-accelerate, and the field application relay will re-apply field so that normal operation is resumed automatically. If field excitation is not removed on pull-out, the motor is apt to stall and, in addition, is subjected to violent torque and current surges. If the driven machine must be unloaded when starting, in order that the motor will accelerate and synchronize, it often is possible to provide an automatic, electrically operated unloader, which can be connected to the field contactor. Then, on pull-out, the automatic removal of field also will unload the machine, so that the motor can resynchronize. The load is then automatically re-applied. The field-removal relay may operate on the abrupt drop in the power factor of the current drawn by the motor as it pulls out of step, or on the increase in line current under this condition, or on the current induced in the field winding as the motor speed drops below synchronous speed.

Means for adjusting d-c excitation applied to a synchronous motor also should be provided. If an exciter is used to supply excitation to a single synchronous motor, adequate control of the excitation can be obtained by means of the exciter field rheostat. However, if a single d-c generator supplies excitation to two or more synchronous motors, a motor field rheostat or tapped resistor must be connected in series with the field winding of each motor for adjustment of the excitation current. Synchronous motor controllers are usually arranged for mounting an exciter field and, where required, a tapped motor field resistor or (on open-type controllers) a motor field rheostat. If a motor field rheostat is required and the control is of the enclosed type, a separately mounted, motor-operated rheostat with only its control switch mounted on the controller is generally recommended.

Usual practice provides synchronous-motor controllers with two ammeters, an a-c ammeter for reading line current, and a d-c ammeter for reading field current. Instruments, such as an a-c voltmeter, indicating wattmeter, or watthour meter, are often valuable additions.

Like induction-motor controllers, synchronous-motor controllers normally have a thermal-type *overload relay*. Time-delay *undervoltage protection* is standard for controllers rated 2200 volts and above; for controllers of lower voltage rating, instantaneous undervoltage protection is standard, but the time-delay type can be obtained.

Controllers of the open type are available, but those furnished with general-purpose enclosing cases are becoming increasingly popular.

TYPES. Synchronous-motor controllers of the following types are commonly used: (1) magnetic full-voltage, (2) magnetic reduced-voltage autotransformer reactor or resistor, (3) semimagnetic reduced-voltage autotransformer, and (4) magnetic part-winding.

Types 1 and 2 are similar to corresponding types of magnetic squirrel-cage induction-motor controllers with the addition of the automatic field control and ammeters described above. Type 3 is similar to the corresponding type of manual squirrel-cage induction-motor controllers with the same additional features.

Magnetic part-winding controllers are arranged to start a motor by energizing only a portion of the complete armature winding and then, after the motor has accelerated, energizing the remainder of the winding in one or more steps. The motor must be designed especially for this type of starting, with a *multiple-circuit* armature winding and sufficient terminal leads to allow energization of the various circuits independently. The effect of this starting method is to reduce the current drawn from the line and the torque developed by the motor at start, giving the effect of reduced-voltage starting without the use of an autotransformer, resistor, or other voltage reducing device. The amount of reduction in torque and current depends on the percentage of the winding energized and also on the characteristics of the individual motor. With some motors the torque is reduced in proportion to the reduction in current, whereas in others a considerably greater reduction in torque occurs. Like reduced-voltage resistor starting, part-winding starting has the advantage that the circuit to the motor is not opened during the starting period, making the method particularly applicable where the starting current limitations are of the increment type. Motors of relatively high voltage in relation to their horsepower cannot be economically designed for part-winding starting. The method is most applicable to low-speed machines of large horsepower and moderate voltage. Most motors and controllers for part-winding starting are arranged to give just one reduced kilovolt-ampere step (two-point starting), but in many cases they can be provided with two, three, or more reduced kilovolt-ampere steps.

AUTOMATIC REGULATORS

By ED S. SMITH [1]

1. TERMINOLOGY

Control and Regulation. Loose use of the terms *controller* and *regulator* as full equivalents is fairly common (Refs. 1–7). However, to avoid the ambiguity resulting from such use, the following terminology is used in this section: *control* is the basic or generic term, thus a valve controls the flow of a fluid through it; *regulation* is control which tends to maintain a given value, whether this is set constant or varied in any manner as, according to a program or schedule, a ratio to some other value, or in any desired manner. For example, the common pressure regulator acts to maintain pressure at a given value, a time-temperature regulator acts to cause the regulated temperature to follow a reference value according to a predetermined schedule, and a flow-ratio regulator acts to control one flow in accordance with the rate of another to maintain their ratio constant.

A typical regulator, diagrammatically shown in Fig. 1, consists basically of a *meter* sensitive to the value of the variable to be regulated, a *control valve* for the rate of a *control agent* affecting the value of said variable, and means connecting the meter with the valve so that the meter governs the valve's position to tend to cause the valve to keep the measurement at a set reference value. Completing the control loop between the control valve and the meter is a *plant* in which there is usually some storage of the control agent, or other source of lag or retardation of the response of the measurement to a change of position of the control valve. Also the basic need for a regulator arises from "disturbances" or changes in "load" of the plant.

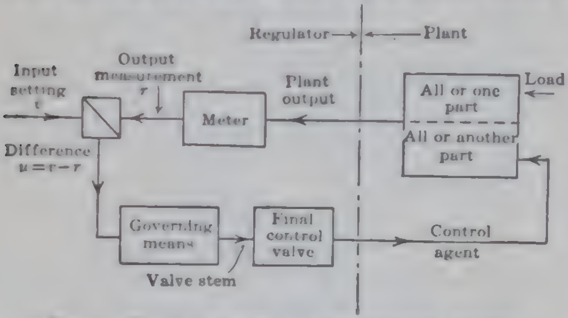

FIG. 1. Block diagram of typical regulated system.

Self-operated and Servo-operated Regulators. In a *self-operated regulator* the meter actuates the control valve whereas, in a *servo-operated regulator*, the meter actuates a pilot or relay which, in turn, controls a servomotor that actuates the final control valve.

A servomechanism (Refs. 8–10), as commonly used, is a regulator-type system in which the emphasis is on having the output position, θ_o, of the final controlled element accurately follow θ_i, that of a variable setting, instead of compensating for the effect of load changes, although such compensation is occasionally also an important factor. Servomechanism theory advanced rapidly during World War II, mainly on the basis of continuously minimizing the difference $\theta = \theta_i - \theta_o$ between the position θ_i of an input or setting element, e.g., a telescopic sight, and θ_o, that of an output or final controlled element such as a gun. This theory, which is more or less directly applicable also to self-operated, but otherwise similar, mechanisms and to regulated systems generally, is treated in the following chapter on servomechanisms.

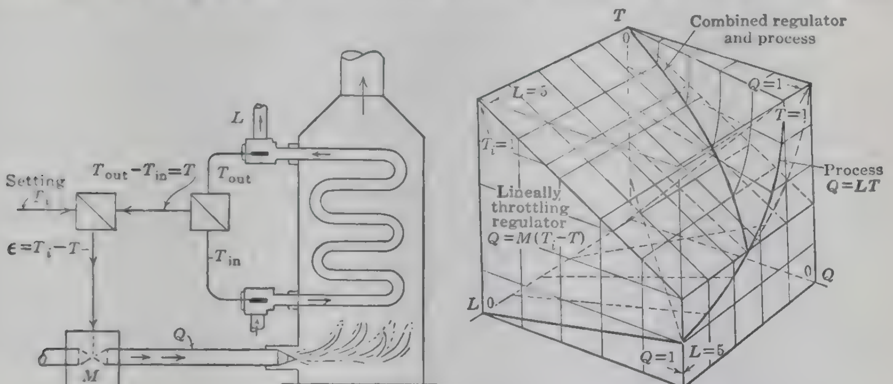
Treatment of the theory of automatic control or regulation in general in the present chapter is properly preliminary, especially for nonelectrical engineers, to the chapter on servomechanisms. Furthermore, there are differences in practice since, in servomechanisms, the plant usually consists of a single element, such as a gun, having relatively high inertia, whereas in process control it usually contains several "capacities" for storing the control agent and occasionally includes several additional sources of lags or retardations.

2. STATIC RELATIONS

The static, ultimate or "potential," effect of a change of load on a regulated plant is independent of any lag or retardation in the system as long as the system is not thereby prevented from settling to rest. Figure 2 shows the static relations for a typical simple regulated process system, comprising, for example, a heating plant in which a temperature rise of T degrees Fahrenheit of a water throughput load of L lb per sec is produced by a heat input $Q = LT$ Btu per sec. System is controlled by a simple proportional, or corresponding, regulator according to the relation $Q = M(T_i - T)$, where T_i is the cut-off value for zero throughput load.

In Fig. 2, the *plant* characteristic appears as a warped surface which has the same shape as the familiar thermodynamic gas surface, i.e., hyperbolic, because $Q = LT$, the *regulator* characteristic appears as an inclined plane, and their intersection is the characteristic of the regulated system. Figure 2 shows that "droop" or "load error" is inherent in proportional regulation, indicated by the heavy dash projection of the intercept on the L : T plane.

Although this three-dimensional presentation shows the static or ultimate relations involved, there is a (fourth) dimensional difficulty involved in showing the transient relations following a change of load on this basis. A working picture of the relations involved may be obtained by plotting the transient response with the time-axis normal to the $Q : T$ plane. It is commoner practice, however, to plot the $L : t$ and $Q : t$ relations on a common grid, which directly relates the cause with its transient response or effect, with still further loss of the physical picture involved.



(a) (b)

FIG. 2. Simple regulated system (*a*), and three-dimensional representation (*b*). (Fig. 2*b* reproduced by permission from *Temperature, Its Measurement and Control in Science and Industry*, Reinhold Publishing Corp., 1941)

Fairchild has shown (Ref. 11) that constant static sensitivity over any desired operating range may be obtained for this and related common regulated process systems, both continuous and batch, by a proportional log-log regulator, for which $Q = M_1/(T_i - T)^s$, where s is a function of said sensitivity alone. A semilog proportional regulator, for which $Q = M_2 \log (T_i - T)$, provides an approximation to the theoretically required log-log proportional regulator for constant overall sensitivity over a wide range, which is generally accepted in practice as satisfactory for process control. The semilog regulator is preferable for flow control, especially where there is appreciable resistance in series with the control valve.

The lineal proportional regulator of Fig. 2 is well suited for the control of liquid level in a reservoir having vertical sides. It also gives closer control than the semilog regulator, where the control valve is by-passed by a fixed resistor (Ref. 12, pp. 48–49).

In throttling control, where the meter and governing means are lineal, the modification of the control valve which suits the plant for a proportional regulator is also suitable for a proportional-speed floating regulator, the stability otherwise generally falling off at low loads. In a floating regulator, the speed of moving the valve is normally slow enough to let the valve settle at its proper control position. In a proportional-speed floating regulator, the speed of the valve is proportional to the error, or difference, between the measurement and the set value to be maintained.

3. TRANSIENT PERFORMANCE

TYPICAL PLANTS. A few of these are included here to bring out their characteristics qualitatively, mostly as to lags, retardations, and attenuations which affect the stability and type of control attainable with conventional regulators. Before taking up these effects, a few of their causes are considered.

Storage of the control agent may exist in the plant. Taking for example level control of a single capacity or reservoir as in Fig. 3, it is inherent that this storage exerts both retardation and attenuation of the response to a movement of its control valve. If the movement of the control valve is sinusoidal, the response of the head or level lags 90 degrees in the absence of "self-regulation" (explained below) and is attenuated to be inversely proportional to the size, i.e., area of air-liquid surface in this example. In other words, a large capacity just before the meter exerts a smoothing effect.

Self-regulation is said to exist when an increase in the inflow to such a system causes the level to rise toward a definite head instead of increasing indefinitely. This can have several causes: flow over a weir or through a resistor with the flow increasing with head. Such a resistor R introduces an in-phase component for the foregoing oscillated-control-valve, single-capacity example, which reduces the phase lag below the 90 degrees due to the capacity C.

Referring to Fig. 3, if the outflow is directly proportional to head, then $q = h/R$. If supply is completely shut off, the head decreases at such a rate that $C(dh/dt)$ is equal to the outflow. Equating these two values,

$$\frac{h}{R} = -C\frac{dh}{dt} \quad \text{or} \quad \frac{dt}{RC} = -\frac{dh}{h}$$

Integrating between the limits $t = 0$, $h = h_o$, and $t = t$, $h = h$,

$$\frac{h}{h_o} = e^{-t/RC}$$

For a sudden, or step, change of the valve position, the retardation may be expressed by the *time constant* $RC = T$, which is the time it would take for the ultimate value to be reached if the initial rate were continued (Fig. 3B and C). For this value of t the corresponding actual value of the head would be, from the relation just derived, $h = h_oe^{-1} = h_o/2.7183 = 0.368h_o$. In other words, this time constant is the same time that is required for the difference from the ultimate value to be reduced to 36.8% of its initial value. (See Fig. 4.) This time constant is also equal to the lag ultimately approached for the same single-capacity system with a constant-velocity, instead of a step, change. In general, self-regulation alone cannot provide the needed accuracy of control but occasionally it is strong enough, with a sufficiently low time constant, to enable stable control to be obtained with a somewhat simpler or less expensive floating control than the proportional control that would otherwise be required. In floating control, the final control valve moves gradually to its proper position, instead of only nearly to it, as it would in proportional control.

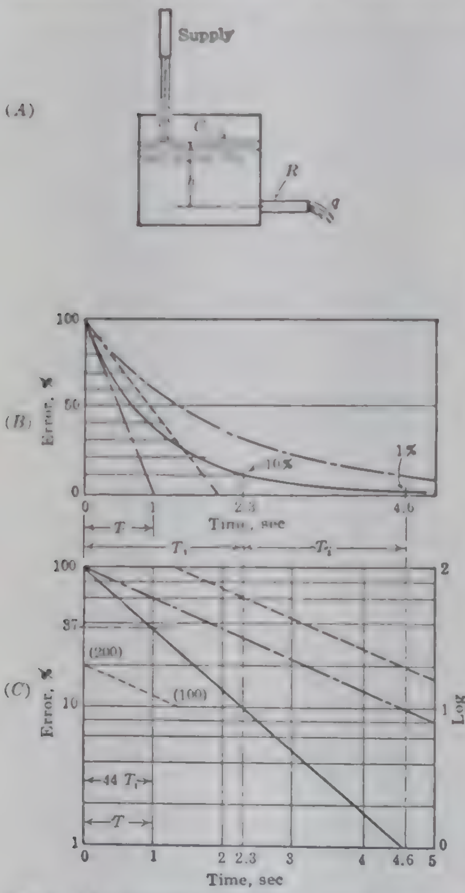


FIG. 3. (A) Capacity and resistor, a single-capacity plant. (B) Fall of head h after the supply is shut off, even-graduations graph. (C) Fall of head h after the supply is shut off, semilog graph. (From *Automatic Control Engineering*, by Ed S. Smith, McGraw-Hill Book Co., 1944, by permission)

Where the plant includes a number of capacities, or storages separated by resistances, their distribution affects the *controllability* of the plant. For example, a two-capacity plant with unequal capacities has more attenuation and hence smoother control when the larger capacity is next to the meter than when it is adjacent to the control valve. A special case, approximated where the components are nearly alike, is one in which the several time constants are equal. This case is generally difficult to control, especially where damped oscillations, rather than an asymptotic or monotonic approach to a final value, occur following an upset. For a two-capacity plant, the contribution of each of the two time constants to the plant's response to a step change is illustrated in Fig. 5.

With a plant having a large number of capacities in series, there is a tendency, as distributed capacity and resistance is approached, to have a virtually direct time lag of the response at the meter to a step movement of the control valve. This outright delay makes stable control difficult or even impossible to achieve with conventional continuous regulators. The initial overshoot, before a counteracting control effect is initiated, tends to be proportional to the dead time. Figure 6 shows that the dead time t_{L3} produced by a dead zone tends to increase directly with the number of capacities.

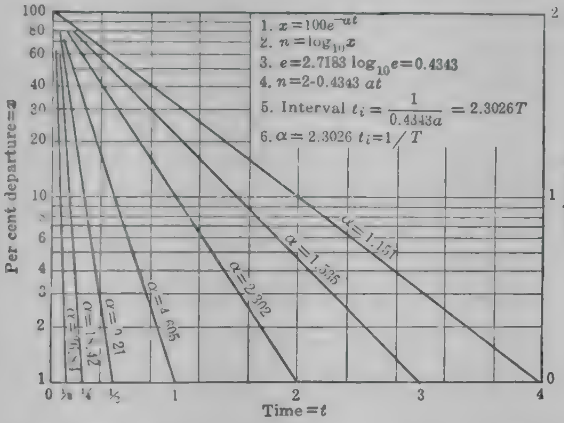

FIG. 4. Asymptotic return paths for various values of $\alpha = 1/T$ for single-capacity plants. (From Automatic Regulators, Their Theory and Application, by Ed S. Smith, in *Trans. ASME*, Vol. 9, No. 4, pp. 291–303, May 1936)

A *direct time lag* also occurs in plants in which a lag exists due to a physical transportation of the control agent from the control valve to the point at which it becomes effective. This is known as "transportation" or "distance/velocity" lag since the delay is equal to the distance divided by the velocity with which the agent is transported.

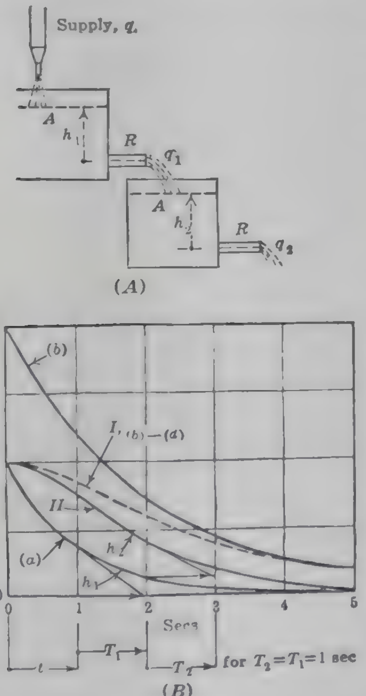

FIG. 5. (*A*) Cascaded tanks, a two-capacity plant, with equal capacities and equal resistors; (*B*) performance as it is not in curve I, and as it is in curve II. (From *Automatic Control Engineering*, by Ed S. Smith, by permission)

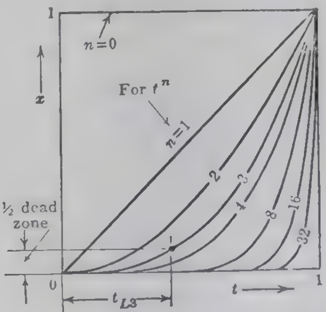

FIG. 6. Initial reaction t^n to a step change. (From *Automatic Control Engineering*, by Ed S. Smith, by permission)

And, in some plants, the response may be erratic for some reason, making the plant hard to control. This may be the case where a thermocouple is exposed to a fluid at different temperatures, which depend upon the vagaries of an unguided thermal circulation.

4. TYPICAL REGULATORS

In practice, regulation is not always accurate to a set value, due to the characteristics of the regulator and/or plant, as is brought out in the following typical cases.

On-and-off regulators convert each drop of a measurement below the set value into an "on" heating impulse which continues as long as the temperature is too low. This sort of regulation is especially effective where a large capacity is located adjacent to the meter and where there is not too much other lag in the system. While this sort of regulator hunts continuously, a relatively large capacity adjacent to the meter is usually provided to keep the oscillations of the measured variable within acceptable limits. Also, in on-and-off control the full-on initial action following each switch operation provides a *liveliness of control* which helps to offset lag in the plant.

The test for stability of a discontinuous or nonlinear regulated system is not whether oscillations completely die out, but whether they drop to unobjectionably low value, an "unstable" discontinuous system being one in which the oscillations build up to a steady objectionably high value. While an on-and-off regulator itself operates to a point, a load produces a droop or change of the average value of the measurement for a given set control value.

Since the amplitude of the oscillations of the measured variable tends to vary inversely with their frequency, a marked improvement in control accuracy can often be obtained by oscillating the control-setting reference itself at a higher frequency than that of the system when the latter is regulated by a simple on-and-off regulator. This improved mode has long been known as Gouy regulation (Ref. 13).

Two-position regulation (discontinuous) is also often used, with a space between the "low" and "high" contacts at the meter providing a dead zone in which oscillations can die out and normally do. When this type of regulation is used on an actual single-capacity heating plant, there is a saw-tooth action from a succession of the initial portions of heating and cooling curves between the contact limits. But upon the addition of a second thermal capacity and resistance, a hunting is set up which tends to pass far beyond these limits (Ref. 12, pp. 28–30). If a floating action is produced by using a constant-speed motor to actuate the control valve, the width of the dead zone can be narrowed by lowering the speed of moving the control valve. However, in practice a limit is soon reached at which such regulation is too sluggish to meet the changes in load on the plant.

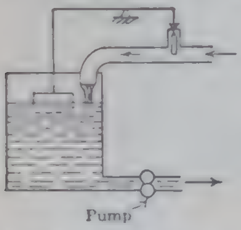

FIG. 7 (*left*). Proportional Control. Stable asymptotic regulation of a single-capacity plant without self-regulation. (From *Automatic Control Engineering*, by Ed S. Smith, by permission)

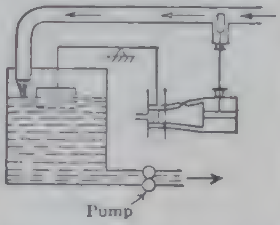

FIG. 8 (*right*). Floating Control. Unstable, steady-hunting regulation of a single-capacity plant without self-regulation. (From *Automatic Control Engineering*, by Ed S. Smith, by permission)

Proportional regulation (continuous), Fig. 7, powerfully tends to stabilize a regulated plant at the expense of load error or droop. In other words, an error is inherent since the movement of the control valve is proportional to such error and consequently cannot completely remove it. The regulator's sensitivity, or ratio of movement of the control valve to the amount of error, may be raised quite high, e.g., of the order of 20, when the plant lag is not unduly large or unfortunately distributed. From one point of view, this droop of the regulator is a useful substitute for inadequate self-regulation in the plant.

Proportional-speed floating regulation (continuous), Fig. 8, is commonly useful where the plant has adequate self-regulation and the lag in the plant is not too great. With a sinusoidal oscillation of the meter, the control valve of such a floating regulator lags 90 degrees behind the measurement (since it follows the *integrated* error), in comparison with the substantially zero lag of a proportional regulator. The importance of this lag may appear from the fact that instability may occur when there is a lag of as much as 180 degrees in the entire regulated system. In other words, such a floating regulator cannot be relied upon to produce stable control of a plant in which the lag can be 90 degrees or more.

Follow-up Link. By the use of a follow-up link, as in Fig. 9, the movement of the control valve is carried back to the pilot valve, with the stabilizing effect of dropping the sensitivity to a finite value as with proportional control. This is substantially attained, with a reduction of the servo lag from 90 degrees for floating control to nearly the zero lag for proportional control, under steady oscillations.

Another factor in stability, loosely expressed, is the sensitivity of the regulator. In the effort to reduce load error it ordinarily is increased nearly to the point (at 180-degree lag) which causes an oscillation circulating around the control loop to increase successively with each time around. The sensitivity of a proportional regulator is theoretically constant, regardless of the frequency of oscillation, while the effective sensitivity of the floating regulator varies inversely with the frequency, which is likewise the case for most plants.

Stability. The philosophy underlying stability of regulation may be somewhat loosely expressed by briefly stating that instability tends to exist when, in passing around a broken control loop, the lag (1) exceeds 180 degrees and the overall sensitivity, or ratio of effect/cause at the ends of the broken control loop, (2) exceeds unity, and (3) decreases with an increase of frequency. This statement is seen to agree with common experience in regulation.

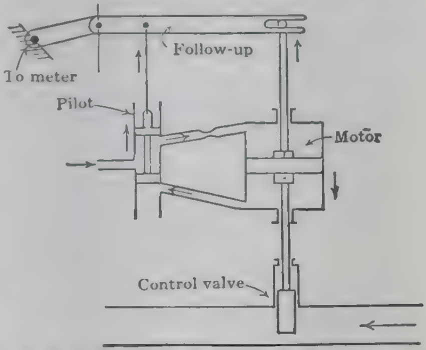

Fig. 9. A follow-up servo regulator; the control valve lags only a few degrees in the normal operation range under steady oscillation of the measurement. (From *Automatic Control Engineering*, by Ed S. Smith, by permission)

A conventional air-operated regulator is shown diagrammatically in Fig. 10. A metering bellows moves a vane relative to a nozzle which is supplied with air through a feed restriction to determine the pressure in the line governing the control valve. When the left-hand end of the vane is pivoted in a fixed journal (not shown), the sensitivity of control is so very high with this essentially proportional control that it breaks down into on-and-off steadily hunting control in the presence of any appreciable lag in the plant.

A relay (not shown) is usually included to provide a larger supply of air to the diaphragm of the control valve than can be controlled directly by the usually small nozzle required for high sensitivity and hence high accuracy of regulation. A "valve positioner" (not shown) is sometimes provided to insure smooth operation of the control valve in spite of mechanical friction; it includes a relay and a follow-up link to the valve stem.

Stable control can usually be obtained at the expense of an increase of load error, by converting this regulator to give low-sensitivity proportional control by pivoting the left-hand end of the vane on proportional bellows connected to the governing pressure. The stiffness or spring action of the bellows insures proportional movements of the pivot and control valve (the reset bellows being omitted).

A reset bellows may be connected through a resistor with the line to provide for the gradual elimination of substantially all the load error resulting from the follow-up movement of the pivot. Thus, following a step change of either the measurement or setting, there is an initial low-sensitivity proportional response which keeps the control valve from overshooting, followed by a further reset (or *integrating*) response during which the control valve asymptotically approaches its final position. On starting up after a shutdown, the reset may cause objectionable overshooting unless it is provided with special limiting or reversing means (not shown).

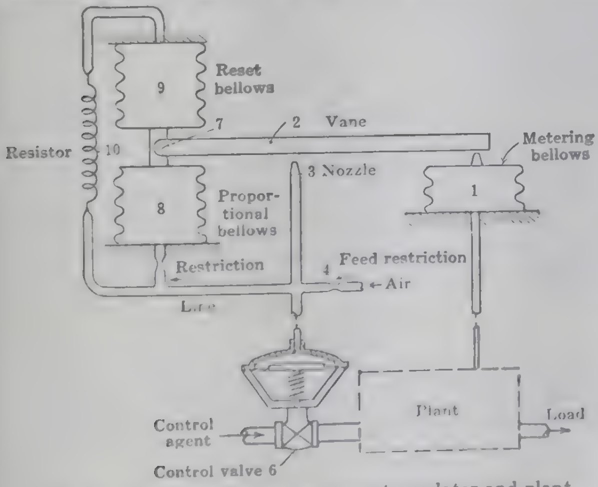

Fig. 10. Diagram of three-component regulator and plant.

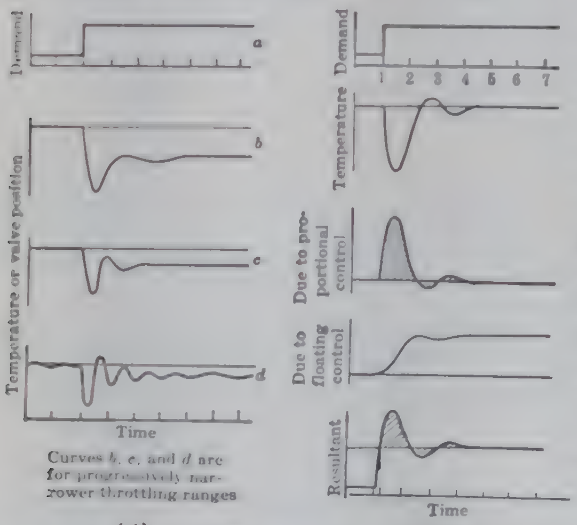
By "reproportion," the addition of a resistor (10) connecting the proportional bellows with the line provides a rate (or *derivative*) action, the resistance of this restrictor being considerably smaller than that of the one connected to the reset bellows, with the result that the time constant of the proportional bellows is much smaller than that of the reset bellows.

The proportional-plus-reset regulator uses the proportional component to obtain stability and the reset component, which is slow relative to the plant, to wipe out gradually the load error due to the proportional component. If the reset speed is unduly increased, the stability is decreased as the relatively lower stability of floating control is approached. But the proportional-plus-reset regulator successfully handles many industrial process plants which are not readily controlled. Figures 11*A* and *B* compare the response to a step change of a typical plant with proportional and proportional-plus-reset regulators, respectively.

The rate, or derivative, component is occasionally added to the proportional and reset components to produce a control effect which occurs sooner than that due to proportional control, this earlier effect being sometimes said to provide "anticipatory" control. A rate component may be considered as, in effect, peeling off one capacity from a regulated multicapacity system (Fig. 6). On a steadily hunting system, or on one with an oscillating input, the rate component removes up to 90 degrees from the phase lag of the system. For one example, a finite rate of change of head occurs in a single-capacity plant as soon as its outflow changes, and the rate component can cause a substantial correcting movement of its inflow control valve before the head has changed enough to build up much of a proportional component. For another example, after an increase of load in a heating system in which considerable metering lag exists, a temperature deficiency accumulates during the lag before the meter responds; then the rate component provides a heat *impulse* to offset the accumulated deficiency, thus leaving the proportional and/or floating components to function as described earlier.



Curves *b*, *c*, and *d* are for progressively narrower throttling ranges

(*A*)

(*B*)

FIG. 11. Response to a step disturbance with proportional (*A*) and proportional-plus-floating (*B*) controls. (From Some Fundamental Considerations in the Application of Automatic Control to Continuous Processes, by E. S. Bristol and J. C. Peters, *Trans. A.S.M.E.*, Vol. 60, pp. 641–650, 1938)

The function of the reset component remains of course unchanged in a three-component regulator. As is shown later, each of the three components is occasionally needed to stabilize a process plant that is unusually difficult to control. A rate component, or some element having a generally similar effect, is needed with most servomechanisms, the rate of movement of the final control element being often used instead of that of the meter.

TYPICAL REGULATED SYSTEMS. The ideal three-component regulator follows the relation

$$-y = R\frac{dx}{dt} + Px + F\int x\,dt \tag{1}$$

where R, P, and F are the rate, proportional, and floating speed component constants. For example, let y be a force exerted on a plant consisting of a damped sprung mass and x be the displacement of the mass M from its position of rest; then

$$y = M\frac{d^2x}{dt^2} + N\frac{dx}{dt} + Bx \tag{2}$$

where N is the damping factor and B the spring stiffness in the plant. Then, after a disturbance of the system,

$$M\frac{d^3x}{dt^3} + (N + R)\frac{d^2x}{dt^2} + (B + P)\frac{dx}{dt} + Fx = 0 \tag{3}$$

after differentiation to convert the integro-differential equation into a third-order differential equation in which, for stability, the product of the inner pair of coefficients must exceed that of the outer, or $(N + R)(B + P) > MF$.

Figure 12 shows the performance of different combinations of inertia M, damping N, and spring stiffness B in the plant with different combinations of rate R, proportional P, and floating speed F components of the regulator, the presence of the different plant components being shown as the abscissa and of those of the regulator as the ordinate. For example, an M plant, i.e., one having no damping or self-regulation, is seen to be unstably controlled by a regulator having only the F, or floating, component (Fig. 13). This instability is readily checked since the product of the inner pair of coefficients is zero, which is obviously not greater than the product MF as required for stability.

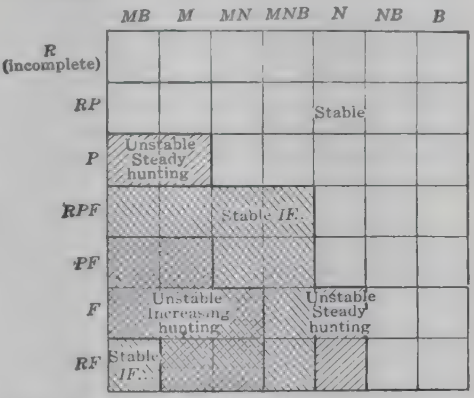


FIG. 12. Performance of a damped-sprung-mass plant with a three-component regulator. (From *Automatic Control Engineering*, by Ed S. Smith, by permission)

Transient Performance. Given the characteristics of such a system, its transient performance may be determined directly from Liu's graph (Ref. 12, pp. 101, 102, 235–244), and vice versa from Kochenberger's (Ref. 12, pp. 244–246), a cubic auxiliary equation being involved.

FREQUENCY RESPONSE ANALYSIS. For a more general approach, that of Nyquist, disconnect the link between the final control element and its actuator and manually oscillate the element at a given amplitude and frequency. On completing the loop through the plant, the corresponding oscillations of the actuator will be of the same frequency and of relative amplitude and phase, which may be used in determining stability.

(b) Operation of the system of (a), no steady hunting but highly unstable with increasing hunting

FIG. 13. A two-capacity system and its performance. (From *Automatic Control Engineering*, by Ed S. Smith, by permission)

Consider the case of **steady hunting,** the critical case between instability and stability. Each successive cycle is of the same amplitude, and the length of the corresponding vector does not increase with time. For this case and following one impulse (at the vector's time position) around the loop, it is manifest that the result must occur just 360 degrees later in the cycle for the stated steady hunting, i.e., at the resonant frequency. Since the control action for regulation is necessarily opposite to its cause (a rise of temperature causing a control action which tends to lower the temperature), an inherent 180 degrees of direction or phase difference, the complemental time lag must be 180 degrees for steady hunting. Referring to the broken control loop having equal amplitudes and 180 degree lag, the broken ends can be connected so that the cyclical impulses are self-energizing and continue without change.

FIG. 14. Nyquist's vectorial diagram of effect/cause. (From *Automatic Control Engineering*, by Ed S. Smith, by permission)

What is true for one impulse part of a sinusoidal wave can be extended by superposition to the others represented by the vector. To have the vector length increase in each cycle is necessary for instability. And an increase of lag beyond 180 degrees is no exception to the general rule that the tendency toward instability increases with increase of lag. In any actual physical system, an increase in frequency tends, as the limit of infinite frequency is approached, to result in a reduction of amplitude toward zero, as can be seen where a mass responds to a sinusoidal force.

Nyquist Criterion. Taking these three considerations together for a system having no negative damping amounts to a practically useful statement of the Nyquist criterion for stability (see Fig. 14). A control system is unstable if the locus of the broken-loop vector for effect/cause spirals inward with increasing frequency in a clockwise direction beyond the "minus one" critical point, the clockwise direction being that for increasing lag. A more extended treatment of the Nyquist approach is given in the chapter on servomechanisms.

5. QUANTITATIVE CONSIDERATIONS

With lineal controlled systems, the response follows ϵ^{-st}, where the natural base $\epsilon = 2.7183\ldots$ and the complex quantity $s = r + j\omega$, where the first term (r) is real and the second $(j\omega)$ is imaginary, with $j = \sqrt{-1}$. Thus the damping is expressed by r, and oscillations are expressed by the angular frequency ω in radians per second, since $\cos \omega t = (\epsilon^{j\omega t} + \epsilon^{-j\omega t})/2$ and $\sin \omega t = (\epsilon^{j\omega t} - \epsilon^{-j\omega t})/2j$ and any phase (ϕ) relation is expressed by sine and cosine components.

In operational terms, s or p is commonly used for (d/dt) since $d\epsilon^{pt}/dt = p\epsilon^{pt}$. And, since $d\epsilon^{j\omega t}/dt = j\omega\epsilon^{j\omega t}$, we can write for the steady oscillation case that $d/dt \cong p \cong j\omega$. The differentiation corresponds to a 90-degree phase lead, while an integration accordingly has a 90-degree phase lag. It may be noted here that the Laplace transforms are $1/p$ times those of Heaviside, the step function being expressed by $1/p$ and **1**, respectively, in the two systems.

Consider a forcing function denoted by $f(t)$ impressed on a unit system whose "impedance" $Z(p)$ determines the response or output $i(t) = f(t)/Z(p)$, just as electric current equals voltage divided by resistance, or $I = E/R$. Instead of impedance, its reciprocal, the transfer function $Y(p)$, may be used, in which event $i(t) = Y(p)f(t)$.

For steady oscillations, the particular solution is as stated above, and for $f(t) = \epsilon^{at}$ this response becomes, for all but the special equal roots case (which can be approximated by nearly equal roots), $i(t) = \epsilon^{at}/Z(a)$. For a forcing function consisting of a number of terms of the ϵ^{at} sort, the steady-state response of a linear system is, by superposition, simply the sum of the individual respective responses to each of said ϵ^{at} terms.

For example (Ref. 12, pp. 276–279), consider a system for which the constants lead to the equation

$$\frac{d^2x}{dt^2} + 2\frac{dx}{dt} + 7x = 2\cos 10t = e^{j10t} + e^{-j10t}$$

Writing $p = d/dt$, the left-hand side of the equation becomes

$$p^2x + 2px + 7x = (p^2 + 2p + 7)x$$

and the impedance is $Z(p) = p^2 + 2p + 7$. The system is subjected to the sinusoidal forcing function for which $a_1 = j10t$ and $a_2 = -j10t$. Then the steady-state response is

$$x_p = \frac{\epsilon^{j10t}}{(j10)^2 + 2(j10) + 7} + \frac{\epsilon^{-j10t}}{(-j10)^2 + 2(-j10) + 7}$$

$$= -\frac{\epsilon^{j10t}}{93 - j20} - \frac{\epsilon^{-j10t}}{93 + j\,20}$$

For the vectors which the denominators denote, the radius is $\sqrt{93^2 + 20^2} = 95.1$ and the angles are, respectively, $\tan^{-1}(-20/93)$ and $\tan^{-1}(+20/93)$. Numerical value of each angle is 0.212 radian = 12.1 degrees; hence the steady-state response may be written

$$x_p = -\frac{e^{j10t}}{95.1\epsilon^{-j0.212}} - \frac{e^{-j10t}}{95.1\epsilon^{+j0.212}}$$

$$= -\frac{2}{95.1}\,\frac{e^{j(10t+0.212)} + e^{-j(10t+0.212)}}{2}$$

$$= -0.021\cos(10t + 0.212) = +0.021\cos(10t + 0.212 + \pi)$$

$$= 0.021\cos(10t + 3.354)$$

Hence at $t = 0$, $x_p = 0.021\angle 3.354$ radians $= 0.021\angle -167.9$ degrees. In other words, the resultant displacement x lags 167.9 degrees behind the imposed sinusoidal force.

In following a sinusoidal forcing function around a control loop, each transfer function $Y(p)$ is taken in turn and, for this series case, we multiply together the amplitudes or radii of the vectors and add their phase angles algebraically, each amplitude being the ratio of output to input for its respective element. Thus if a regulator G creates a torque $Q(t)$ which acts upon a plant H, the overall loop transfer characteristic function is simply $G(p)H(p)$, or GH as usually written, since $Q(t) = G(p)(t)$ and $\theta_o(t) = H(p)Q(t) = G(p)H(p)(t)$ or GH and $GH = \theta_o/\theta$, where the deviation (*not* error) is $\theta = \theta_i - \theta_o$. This θ convention takes care of the "minus one" control relation and leaves only time, or phase, *lags* in the results of the analysis.

The transfer function $Y(p)$ is seen to be the "admittance" or inverse of impedance $Z(p)$. For a loop in which part of the system is in shunt, we can simply add vectorially the transfer function $Y(p)$, or $Y(j\omega)$, vectors for the shunt portion, and proceed as before for any series portion, following conventional rules for shunt and series impedance networks with due regard for the stated inversion. Using $j\omega$ instead of p in the overall loop transfer function θ_o/θ permits us to use the available network laws, including Kirchhoff's (Ref. 14) and that of duality (Ref. 14, pp. 63–67), in handling the more complicated multiple-loop systems. Some algebraic simplification results from using θ/θ_o, the inverse of the above expression, in complicated networks.

SERVOMECHANISM EXAMPLE. Consider an example (Ref. 15) (Fig. 15) of a simple servo system in which a rotatable mass is positioned by an electric motor whose supply voltage v_a is governed by a proportional regulator having an amplifier that is sensitive to a voltage v proportional to the positional deviation θ. Going around the loop: the amplifier has a static sensitivity or "gain" of 41.5 and a time constant of 0.04 sec so that its transfer function is $v_a/(v - v_s) = 41.5/(1 + 0.04p)$, where the time constant has the usual sense of the time required to complete a response if the initial rate persisted.

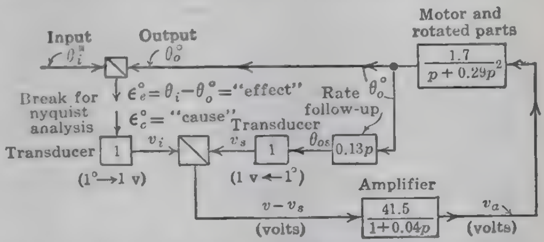

FIG. 15. Block diagram, including output-rate stabilizing means. (From *A Method for the Design of Automatic Controls*, by J. D. Peterson, ASME, Ref. 15)

The inertia of the motor, rotating mass, and their connecting gearing can be lumped under a p^2 term representing the acceleration produced by the torque q. The motor produces a static torque proportional to the voltage v_a, which is determinable from a test at stall. When running, the available torque of a typical servo motor falls off in proportion to the speed, as expressed by a subtracted p term, also determinable from knowledge of the full speed at no load. The transfer function for this idealized lumped motor, rotatable mass and gearing unit, is $1.7/(p + 0.29p^2) = \theta_o/v_a$ or $-\theta/v_a$ for a zero value of θ_i.

In the system of Fig. 15 less the "rate follow-up," breaking the control loop between the rotating mass and the amplifier, and feeding in as a "cause" an oscillating θ_c of one radian amplitude through a transducer to the amplifier at a frequency of 10 radians per sec, the voltage output v_a follows from

$$\frac{v_a}{\theta_c} = \frac{41.5}{1 + 0.04(j10)} = \frac{41.5}{1 + j0.4} = \frac{41.5}{1.076\angle 22.0^\circ} = 38.5\angle -22.0^\circ,$$

having a lag of 22.0 degrees, and the "effect" on the plant (motor-gearing) output follows the relation

$$\frac{-\theta_e}{v_a} = \frac{-1.7}{j10 + 0.29(j10)^2} = \frac{-1.7}{j10 - 29} = \frac{-1.7}{30.7\angle -19.1^\circ} = -0.0554\angle 19.1^\circ$$

Hence the overall transfer function, except for the control reversal of sign, is $-\theta_e/\theta_c = (-0.0554\angle 19.1^\circ)(38.5\angle -22.0^\circ) = -2.133\angle -2.9^\circ$, or $2.133\angle -182.9^\circ$, or a *lag* of slightly more than 180 degrees. If the $\theta = \theta_i - \theta_o$ unit is included, the "effect" θ_e is seen to occur 362.9 degrees later than its "cause" θ_c.

And for $\omega = 10$ radians per sec, the locus point is at about 180 degrees lag, with the effect $-\theta_e$ equal to about twice its cause θ_c. And likewise for $\omega = 15$ radians per sec, $-\theta_e/\theta_c = 0.91\angle -198.1^\circ$ so that, for about the same value of effect and cause, the effect *lags* more than 180 degrees behind its cause. Since these values show the overall loop transfer locus to be spiraling in toward the center and outside the "minus one" point, which is said to be "enclosed" (Fig. 14), the Nyquist rule establishes that this system is unstable.

The overall loop transfer function for this unstable case may be written directly for convenience in plotting the locus, as $\dfrac{-\theta_e}{\theta_c} = \dfrac{70.5}{p(1 + 0.29p)(1 + 0.04p)}$. The system may be stabilized by either (1), at the expense of control speed, increasing the gear ratio to, say, thirteen times the original value when, neglecting any change in the gearing's inertia, the overall gain becomes $70.5/13 = 5.42$, or (2), at the expense of an increase of load error, decreasing the amplifier gain to $41.5/13 = 3.19$.

Alternatively, the system may be stabilized with better performance by adding a follow-up loop for the motor speed (see Fig. 15), in which a speedometer element moves 0.133 degrees for 1 degree per sec velocity of the rotating mass, for which $\theta_{os} = 0.133p\theta_o$ and the transfer function is $\theta_{os}/\theta_o = 0.133p$. Since this ratio is dimensionless and p has the dimensions of inverse seconds (sec^{-1}) for (d/dt), that of 0.133 is seconds. A "transducer" means is provided for converting θ_{os} to a corresponding voltage v_s. Thus, however obtained, a voltage is generated proportional to the output shaft velocity, and imposed on the portion of the amplifier which receives the voltage proportional to the "error."

Since this rate component θ_{os} is subtracted from the error $-\theta_e$ and the difference fed to the amplifier,

$$\theta_o = \left(\frac{1.7}{p + 0.29p^2}\right)\left(\frac{41.5}{1 + 0.04p}\right)(-\theta_e - 0.133p\theta_o)$$

$$\frac{\theta_o}{-\theta_e} = \frac{\dfrac{70.5}{p(1 + 0.29p)(1 + 0.04p)}}{1 + \dfrac{9.38}{(1 + 0.29p)(1 + 0.04p)}}$$

for which the locus spirals in inside the "minus one" point, crossing the 180-degree axis at about -0.25, which shows that the system is now highly stable.

Another use of the locus diagram, proposed by Harris (Ref. 16), is as follows: On it are plotted circles for constant values of $M = \left|\frac{\theta_o}{\theta_i}\right| = \sqrt{\frac{R_o^2 + x_o^2}{R_i^2 + x_i^2}}$ for $\frac{\theta_o}{\theta_i} = \frac{R_o + jx_o}{R_i + jx_i} = \frac{\theta_o/\theta}{1 + \theta_o/\theta} = \frac{GH}{1 + GH}$ and circles for the θ_o/θ_i phase angle $\phi = \tan^{-1}(x_o/R_o) - \tan^{-1}(x_i/R_i)$. These circles give the value of M and ϕ wherever crossed by the locus. Where the locus is tangent to an M circle near the minus one point, there is a tendency for the system to oscillate at the frequency for the locus at the point of tangency. For example, for the stable single-loop system discussed earlier having a value of overall gain of 5.42, the locus is tangent to an M circle at $\omega = 4$ radians per sec, which is the angular frequency of the damped oscillatory transient of this system. For a given class of system, the amount of a transient's initial overshoot following a step change is proportional to the value of M of the thus-tangent M circle.

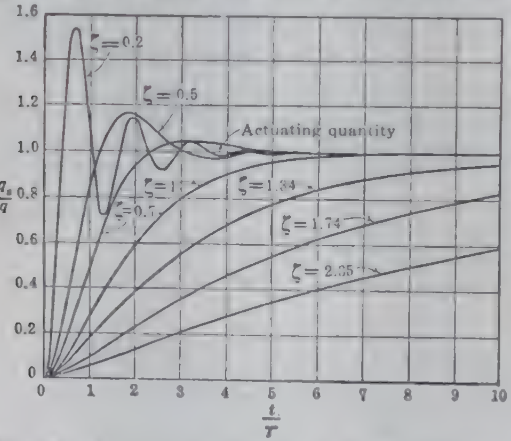

FIG. 16. Instrument response to a step function. (From Design Factors Controlling the Dynamic Performance of Instruments, by C. S. Draper and G. P. Bentley, *Trans. ASME*, Vol. 62, pp. 421–432, July 1940)

RESONANCE. Figure 16 shows the transient response of a damped (N) sprung (B) mass (M) to a step change of force, where the damping ratio $\zeta = \frac{N}{N_c} = N/2\sqrt{MB}$ and the characteristic time $\tau = 2M/N$. Figure 17 shows the transient performance of this same plant or instrument to a suddenly applied, lineally increasing force, a much less drastic change. Figure 18 shows the steady-state response of this same plant to a sinusoidal force, with the noteworthy change of phase from 0 to 180 degrees as resonance is passed with increasing frequency for an undamped mass.

Analogs in control are especially useful in working with systems containing nonlinearities. They are alternate physical means for obtaining the same mathematical relations as for the prototype. For example, the mechanical system having the force equation

$$M\frac{d^2x}{dt^2} + N\frac{dx}{dt} + Bx = f$$

has for an analog an electrical system having the voltage equation

$$L\frac{d^2q}{dt^2} + R\frac{dq}{dt} + \frac{1}{C}q = e$$

or

$$L\frac{d^2i}{dt^2} + R\frac{di}{dt} + \frac{1}{C}i = \frac{de}{dt}$$

where q and i are respectively expressed in coulombs and amperes (Refs. 14, pp. 67–70, and 12, pp. 120–125). The correspondence of the different physical elements is exact when the proper dual (Ref. 14, pp. 63–67) is chosen.

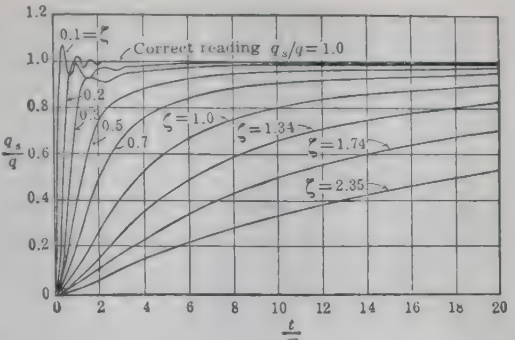

FIG. 17. Lineal forcing function; variation with time of actual reading as fraction of true value of actuating quantity. (From C. S. Draper and G. F. Bentley, *loc. cit.*)

In a servo-controlled system, especially with a proportional speed floating servo, the stabilizing effect of a dead zone is small since the interruption of hunting oscillations occurs in each cycle only near the point where the velocity of the final control valve is a minimum (Ref. 12, pp. 84–85). But such a system may be strongly stabilized by interrupting the motion of this control valve for a like interval in each swing when there is a reversal of trend of the measured variable, since this coincides with the maximum velocity of the control valve for an integrating servo of the type mentioned above, which lags 90 degrees behind the measurement.

Another powerful stabilizing means is by temporarily shifting the control point in the direction of a change so that the meter tends to stop the final control valve when the measurement is still appreciable but the measured variable has actually returned to the set value.

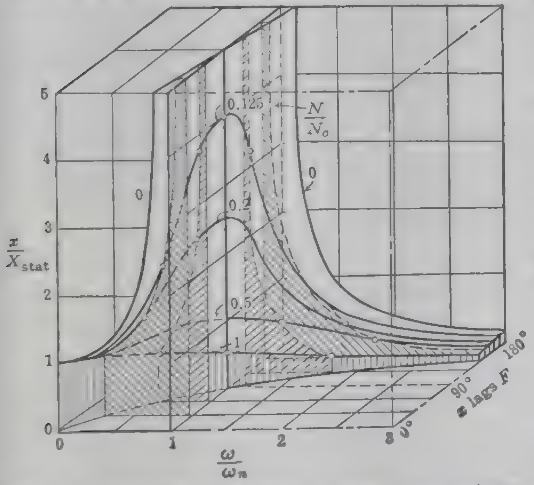

FIG. 18. Performance of a damped-sprung mass under an oscillating force input. x is the amplitude of the response. (From *Mechanical Vibrations*, by J. P. Den Hartog, McGraw-Hill Book Co., 1944, by permission)

6. PROCESS CONTROL

GENERAL. To illustrate the nature of the problem which a regulator has to solve, consider the process control system of Fig. 19 in which the load $L(t)$ affects a part H_a of the plant H, with a resultant effect at the meter of $x_L = H_aL$ if the regulator did *not* operate. This x_L can be considered as equivalent to a change of the input x_i so that the net input is $x_{in} = x_i - x_L$. The effect at the meter due to the difference θ (following the servomechanism convention) in passing around the loop of the system is simply $x_s = -GH\theta$. Hence for $\theta = x_{in} - x_s = x_i - x_L - x_s$ and, letting the setting x_i be steady at a zero reference value,

$$\theta(t) = -H_aL(t) - GH\,\theta(t) \quad \text{or}$$

$$-\theta(t) = \frac{1}{1+GH}H_aL(t) = \frac{1}{1+GH}x_L$$

the stability being determined by the loop term (GH) above as for other systems. For purposes of analysis, some nonlinear systems may be virtually linearized by throwing their nonlinearities into the load. Dr. Claude E. Shannon has noted that a switching system may

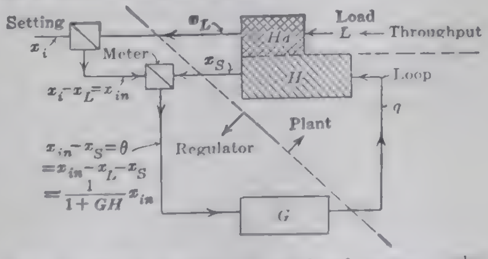

FIG. 19. Block diagram of regulated system under load.

be replaced by an otherwise similar continuous one with a square-wave load of different frequencies and "on" to "off" duration ratios.

EXAMPLE. The plant H may consist of two tanks and associated resistors in series or cascade (Ref. 12, pp. 22 and 93–95), with the load an independently variable flow q_L into the second tank whose level is to be regulated. If, as in Fig. 20, there is no appreciable reaction of the second tank's head on either the flow from the first, or of the first tank's head on the controlled flow q, the relations are relatively simple. Note that this case also corresponds to that of an idealized governed engine which has been extensively treated elsewhere (Ref. 17).

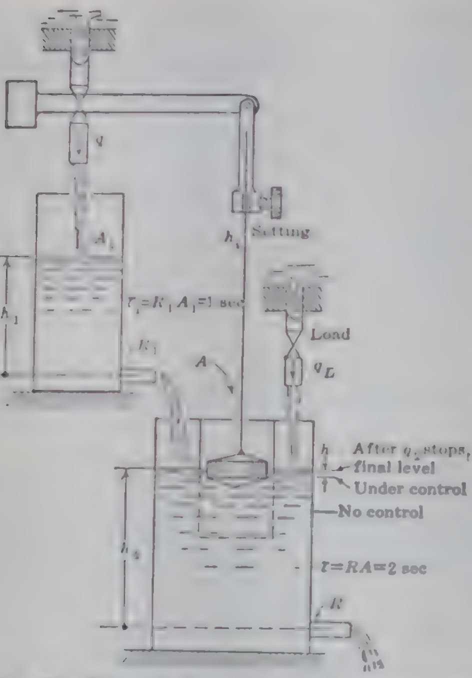

FIG. 20. Diagram of two-capacity plant with proportional regulator for h_2.

The upstream tank has area $A_1 = 1$ ft² and resistance $R_1 = 1$ sec per ft², with a resultant time constant $\tau_1 = 1$ sec. Likewise, the second tank has $A = 2$ ft², $R = 1$ sec per ft², and $\tau = 2$ sec. In both cases, the outflow is substantially proportional to the head. A 1-ft change of level in the second tank operates the control valve to cause a change of the flow rate q of 8 ft³ per sec. The load q_L is a 1 ft³ per sec flow rate into the second tank.

TRANSIENT ANALYSIS. Starting at $t = 0$ with the system in equilibrium, q_L is suddenly stopped. When this occurs, the level response in the second tank would follow a $1e^{-t/2}$ curve if the control valve did not operate.

Since $G = 8$ and $H = \dfrac{1}{(1+p)(1+2p)}$, by superposition, with the control valve operating and the head setting unchanged, the deviation from the final position is $h(t) = \dfrac{1}{1+GH}e^{-t/2} = \dfrac{1}{1+\dfrac{8}{(1+p)(1+2p)}}e^{-t/2} = \dfrac{p^2+p+0.5}{p^2+1.5p+4.5}e^{-0.5t}$. The numerator operates directly on the exponential term by simple differentiation since $p \cong d/dt$, without departing from real time constants.

But the denominator indicates that *damped oscillations are present*, since it corresponds with $p^2 + 2\zeta\omega p + \omega_n^2$, where the undamped natural frequency $\omega_n = \sqrt{4.5} = 2.121$ radians per sec and the damping ratio $\zeta = 1.5/(2 \times 2.121) = 0.3537$, so that the oscillation $e^{-\zeta\omega t}\cos(\omega t + \phi)$ becomes $e^{-0.3537\times 2.121t}\cos(2.12t + \phi)$ or $e^{-0.75t}\cos(2.12t + \phi)$, neglecting the usually slight increase of the actual frequency due to damping. The relatively high value of 8 for the gain or sensitivity is seen to be the cause of the oscillations, and the *static error* is $1/(8 + 1)$ times that for the system if the regulator did not operate.

While the foregoing "crowbar" analysis gives a generally adequate idea as to the nature of the transient response and stability, the complete solution may be obtained by any familiar method of solving differential equations.

Alternatively, the **frequency response** may be used to determine the stability. Breaking the control loop and oscillating the control valve at the system's natural frequency of 2.121 radians per sec,

$$\frac{-\text{effect}}{\text{cause}} = GH = \frac{8}{(1+2j\omega)(1+j\omega)} = \frac{8}{(1+j4.242)(1+j2.121)} =$$

$$\frac{8}{(4.36\angle 76.7^\circ)(2.345\angle 64.8^\circ)} = 0.783\angle -141.5^\circ$$

which values are on the stable side of the Nyquist "minus one" point.

An effort has been made in this treatment of control to cover the general theory common to all types of regulators and servomechanisms, as well as enough instances of practical use to facilitate its application in any particular field. In its short space, considerable ground is covered and a number of references included so that its user can follow the subject as far as is necessary. As it indicates, regulation or control is not a science but, instead, one of the more difficult engineering arts (Refs. 18–20).

SERVOMECHANISMS

By HERBERT HARRIS, JR.

A SERVOMECHANISM is an automatic system used for the control of mechanical position. Its functions are *torque amplification*, *remote data transmission*, and the *conversion of physical measurements into mechanical position*. It is distinguished from other possible systems which meet this same definition by its closed cycle character, illustrated by the block diagram of Fig. 1 showing the components and direction of signal flow.

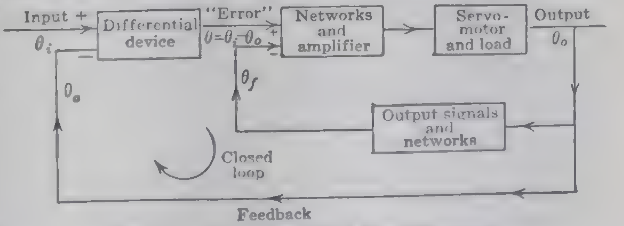

Fig. 1. Servomechanism block diagram.

The *output* or mechanical load is driven by the *servomotor*. The torque of the servomotor is controlled by the output of the amplifier which receives several signals as an input, the principal one being that from the differential device. The *differential device* or *error-measuring device* takes the difference between the actual output position and the desired or *input* position. This difference is called the *deviation* or "*error*." It is this return of the output position measurement through the differential device and then on to control the motor which forms the *closed loop* or *closed cycle* which is characteristic of servomechanisms. Various networks may be interposed in the amplifier or other signals added to its input to provide stability and other special characteristics as described later.

TYPICAL APPLICATIONS (Ref. 1).

1. In some industrial recorders the output or pen is positioned by a servomotor under the control of an amplified voltage. This voltage is the difference between an input

voltage, say from a thermocouple, and a potentiometer voltage which is proportional to pen position. This is an example of the conversion of a physical measurement into a mechanical position.

2. A profile milling machine has the work piece positioned by a servomotor in such a way that it follows a model or pattern over which a light feeler travels. This is an example of a *torque amplifier* or *follow-up.*
3. Guns weighing many tons are positioned very precisely by an operator turning a light handwheel. When, as sometimes happens, the operator or an automatic gun position computer is at a remote position the servo system also includes a data-transmission feature.

7. SERVOMOTORS

The servomotor which provides the mechanical force for positioning the output is usually especially designed so that large output power may be controlled by a low-power signal or force. Among the numerous types are the following:

1. Two-phase motors are controlled by placing one winding across the a-c line and driving the other by an electronic amplifier with a 90-degree out-of-phase voltage. These motors are usually used in the range up to about $^{1}/_{20}$ horsepower for applications requiring high acceleration capabilities.
2. Alternating- and direct-current commutator-type motors are used by controlling the field excitation through an electronic amplifier. These motors are used most often in the $^{1}/_{100}$ to $^{1}/_{5}$ horsepower range.
3. Motor-generator sets are used for the control of a commutator-type motor with fixed field excitation. The armature current is supplied by a generator which is field-excited through an electronic amplifier. These sets are used from about $^{1}/_{4}$ horsepower into the multihorsepower region.
4. Hydraulic or pneumatic pistons are used as servomotors by valving high-pressure oil or air to one side or the other. The valves can be moved by small solenoids or electric motors under electronic control since the pressures on the valve are balanced so that only small driving forces are required. Pistons are used for applications which do not require continuous motion in one direction.
5. Variable-displacement hydraulic pumps and motors are common in the multi-horsepower region. The displacement of such a pump is controlled by varying the stroke of the pistons or vanes by mechanical means. An electric motor or solenoid, sometimes followed by a small hydraulic servo, is used for this purpose.

8. DIFFERENTIAL DEVICES

The function of a differential device (Ref. 1) is measurement of "error" or deviation of the servomotor's actual position from the position it should have. To simplify terminology, the servomotor position is called the output (θ_o) while the desired position is called the input (θ_i). The deviation or "error" (θ) is the difference between the two,

$$\theta = \theta_i - \theta_o \tag{1}$$

This equation is conventional for servomechanism theory. The deviation of "error" ($\theta_i - \theta_o$) for servomechanisms is the negative of the error ($\theta_o - \theta_i$) generally used for instruments. "Error" is hereinafter used without this distinction as to sign. Examples of differential devices include the following:

1. A mechanical planetary gear differential is often used when both the input and output are easily coupled shaft rotations. Potentiometers or inductance variation pick-offs are used for converting the resulting mechanical motion into various electrical signals.
2. Variation of the airgap of inductive or capacitive elements is used when the two members may be placed on the input and output respectively and the differential movement is small (0.00001 in. to 0.1 in.). This is a particularly useful pick-off or take-off for a differential device such as a gyroscope, which must be lightly loaded. A variety of circuits may be used for the conversion of the parameter variations into voltage changes.
3. When the input and output are physically separated by such a great distance that mechanical coupling is not desirable, some means for remote data transmission must be included in the differential device. *Synchronous units* or *synchros* (Refs. 1 and 2), manufactured under trade names such as *Autosyns*, *Diehlsyns*, and *Selsyns*, provide this function and are commonly used.

Synchronous units are small motor-type units with a single-winding rotor and a three-winding stator wound similarly to that of a three-phase motor. Two such units are used in transmitting data. The two stator windings are connected together, one rotor being connected across the a-c line and the other providing the electrical error signal for the servo amplifier. One rotor is rotated by the input and the other by the output.

When connected as described, the rotor connected to the a-c line sets up a magnetic field which induces voltages in the three stator windings. These voltages cause currents to flow in the stator of the other unit and set up a parallel magnetic field. The second rotor then has an induced voltage proportional to the cosine of the angle between its axis and that of the magnetic field. The zero-error position is taken at the zero-voltage point when the two rotors are 90 degrees apart. Thus the two rotors must be turned in synchronism in order to maintain the zero-error voltage. The voltage output is proportional to the sine of the error angle, and the direction of error may be determined by the phase relative to that of the a-c line. Alternating-current motors reverse torque with a reversal of the control-voltage phase, but d-c motors require the use of an electronic circuit known as a phase-sensitive detector or "discriminator."

These units are manufactured with a large variety of characteristics. In determining which units to use, it is necessary to specify line voltage, line frequency, maximum speed, number of outputs to be connected to one input, and accuracy. Normally the error of these units is about $^1/_4$ degree, but at least one manufacturer has been able to improve this by a large factor.

When greater accuracy is required, it is common to use the *fine* and *coarse* system of data transmission. Two additional synchro units, wired in the same way as the first, are geared to the input and output to turn faster by some factor such as 25 : 1. Thus a small error provides a signal 25 times as great from these *fine* units, and an accuracy improvement by a factor of 25 is achieved. However, these *fine* units have 24 spurious zero error positions occurring at each revolution when the error is a multiple of 360/25 degrees. These spurious positions are eliminated by the original or *coarse* set of synchros which is connected directly to the input and output shaft. A mixing circuit is used in conjunction with these two signals so that the servomechanism ignores the *fine* signal until the *coarse* signal is near zero and then the *fine* signal is used for the precise setting at zero error.

Synchronous units of a special design may also be used for the direct transmission of mechanical position. If both rotors are connected to the a-c line and the two stators are connected together, the two rotors will tend to line up with a force proportional to the sine of any angular difference between the two. This system is used only when the precision and large output force of a servomechanism are not needed.

9. TRANSIENT RESPONSE

As shown in Fig. 1, the simplest servomechanism would have the servomotor torque controlled by the error signal alone, either by a continuous or an on-and-off action.

TWO-POSITION CONTROL (Ref. 3) refers to a system which makes use of switch contacts in such a way that the servomotor exerts its maximum corrective torque whenever the error becomes greater than some preset value. Between the two switch points controlling the opposing directions of torque is a dead zone which does not call for any torque. Servomechanisms of this type have the serious disadvantage of hunting or oscillating when the dead zone is made small, in order to provide more precise control. If one contact is closed long enough for the motor to build up an appreciable velocity, the load inertia will serve to carry it past the dead zone and to enter the region of the opposing contact at high speed. The torque then reverses, but again the motor will build up speed in the new direction and run across the dead zone. Unless friction is present, which produces large power loss, hunting may continue indefinitely. Many early servomechanisms were of this type but they have been gradually displaced by continuous control for better performance. By the addition of devices which move the contact points back and forth as a function of motor speed and vibrate them to remove errors due to the dead zone, it is possible to retain the advantages of contacts in providing simple control of large power and still obtain some of the properties of continuous control.

PROPORTIONAL CONTROL (Refs. 4 and 5), the simplest example of a continuous control, provides servomotor torque proportional to the error signal. In order to keep the error small, the proportionality constant must be made large so that large corrective and accelerating torques are available. Unless sufficient damping friction is present, this system will also oscillate just as a spring-mass combination would.

A servomechanism with proportional control alone is rarely used except for applications in which the motor is only lightly loaded and the input does not experience high accelerations. The proportionality constant cannot be increased beyond the point where the oscillations do not damp out sufficiently fast, and then the response is sluggish and external loads produce large errors. In order to make full use of the possibilities of continuous control the torque must be made a function of signals other than just the error. The following analysis illustrates this.

Consider a servomotor and load having a moment of inertia J which requires a torque $J\,d^2\theta_o/dt^2$ for acceleration; also, either the load has friction which increases with speed, or the motor has a speed-torque characteristic which drops with speed such that the torque available for acceleration is reduced by $f(d\theta_o/dt)$. Then if the controlled torque $K_o\theta$ is proportional to the error, the following equation applies: *

$$K_o\theta = J\frac{d^2\theta_o}{dt^2} + f\frac{d\theta_o}{dt} \tag{2}$$

If this is combined with eq. 1 relating the input, output, and error,

$$J\frac{d^2\theta}{dt^2} + f\frac{d\theta}{dt} + K_o\theta = J\frac{d^2\theta_i}{dt^2} + f\frac{d\theta_i}{dt} \tag{3}$$

Equation 3 allows the error to be determined for any desired input motion. Many classical and operational methods (Refs. 5 and 6) are available for the solution, involving the solution of the *characteristic equation* obtained by setting $\theta_i = 0$ and replacing the operation (d/dt) by the operator p. This yields

$$p^2J + pf + K_o = 0 \tag{4}$$

The roots of this equation determine the modes of response for the system. In this case the roots are

$$p = -\frac{f}{J} \pm \sqrt{\left(\frac{f}{2J}\right)^2 - \frac{K_o}{J}} = -\zeta\omega_n \pm j\omega_n\sqrt{1-\zeta^2} \tag{5}$$

where

$$\omega_n = \sqrt{\frac{K_o}{J}} \quad \text{and} \quad \zeta = \frac{f}{2\sqrt{K_oJ}} \tag{6}$$

With these roots the response for θ will have a transient term $Ae^{-\zeta\omega_n t}\cos(\sqrt{1-\zeta^2}\,\omega_n t + \phi)$ in addition to a particular solution determined by the input motion. Both A and ϕ are determined by the initial conditions.

ω_n is called the *undamped natural frequency* since it is the frequency of oscillation that occurs when the damping is zero ($f = 0$).

ζ, called the *damping ratio*, expresses the ratio of damping present to that required for *critical damping* which exists when there are two equal real roots. When ζ is greater than unity, the system is overdamped, with real unequal roots, and no oscillatory term is present.

Figure 2 shows the response of this servomechanism in returning from an initial error, as might occur after forcing the output shaft out of position and then releasing it. For a motor and load with a given J and f, the response becomes faster as K_o is increased, since ζ decreases and ω_n increases, thereby shortening the time scale. Eventually, however, ζ will become too small, and the response will be oscillatory and have too much overshoot.

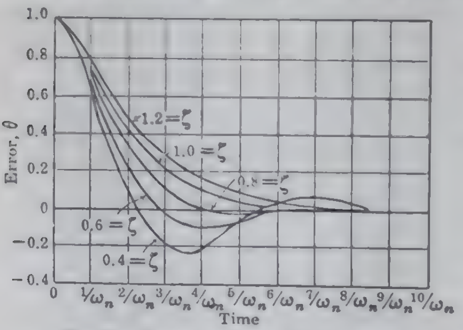

FIG. 2. Response to an initial error.

If the input is rotated at constant speed, the output will follow at the same speed after a transient similar to that just described has died out. However, a fixed error, known as the *constant velocity error* or *speed lag*, will remain. It is generally measured as a time constant defined as the lag per unit of velocity and in this case is equal to f/K_o.

Another error that may be present, called the *static error*, represents the size of error that must be present before the servomotor torque ($K_o\theta$) can overcome the dry friction F which is present. The error may have any value within the static-error zone F/K_o without producing any corrective action.

---

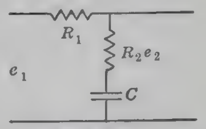
* This analysis and the remainder of the chapter assume that, for small motions, the system may be considered linear.

The design for the simple proportional-control servomechanism requires the choice of a value for K_o. Increasing the sensitivity K_o will reduce the static and constant velocity errors as well as the response time, but too large a value will cause an oscillatory response. A satisfactory compromise cannot generally be found for applications other than light instrument servomechanisms. An increase in the damping coefficient f is not often useful since it represents power loss as well as an increase in speed lag.

For most applications a more complex control system is necessary such as the use of a derivative control to provide the necessary damping without the disadvantages of friction. If the control torque is made equal to $K_o\theta + K_1(d\theta/dt)$, the second term is called a *derivative control*. The characteristic equation then becomes $p^2J + p(f + K_1) + K_o = 0$ so that K_1 acts similarly to the friction for damping. However, K_1 does not add to the speed lag. Thus the sensitivity may be increased and nonoscillatory response still achieved. The derivative control term may be obtained by measuring the speeds of the input and output shafts, but, more often, a network operating on the error signal is used to produce an approximate derivative.

The increase of sensitivity and provision of damping by a derivative control has its limits also. Eventually the response becomes so fast that various other factors must be included in setting up the equations of motion, since they then begin to have an appreciable effect. In particular, various response retardations or delays, such as those occasioned by the time required to build up current in a motor field due to its inductance, become important. When these delays and others due to the introduction of demodulators and networks in the amplifier are taken into account, the degree of the characteristic equation becomes higher than the second, and the addition of a derivative control does not always provide the necessary damping. This is also true of more complicated servomechanisms such as hydraulic servomechanisms which have an electric motor as well as a hydraulic torque amplifier in the loop ahead of the servomotor.

A slow-response type of control is often used to reduce the speed lag and static error without increasing the speed of response to the point that internal response delays become important. If the control torque is $K_o\theta + K_1(d\theta/dt) + K_{-1}\int\theta\,dt$, the last term is called an *integral control*. For any steady errors, the torque gradually builds up in magnitude and can provide the necessary steady driving torque even after θ becomes zero. In practical cases, the integral cannot be taken exactly and the control acts more like a slow increase in K_o and the steady error cannot become exactly zero. Figure 3 shows a circuit that gives this integral type of control.



$$\frac{e_2}{e_1} = \frac{1 + R_2Cp}{1 + (R_1 + R_2)Cp};\ R_1 \gg R_2$$

FIG. 3. Integrating type network.

With a characteristic equation of high degree, the concepts discussed in the foregoing still apply, but they are not easily worked into a design procedure. The characteristic equation may be factored into a series of quadratics, each of which has its own undamped natural frequency and damping ratio. Unfortunately, above the fourth degree this factorization can be carried out only numerically and even then only with considerable time expenditure. One set of relations between the coefficients, known as *Routh's criterion* (Ref. 6), is often used to determine if any of the damping ratios are negative, a negative damping ratio indicating an *unstable* system in which the oscillations build up rather than die out.

In order to facilitate the transient analysis of complicated systems, differential analyzers (Refs. 7 and 8), which automatically solve the equations of motion, are finding considerable use. However, for the synthesis and design of servomechanisms, another approach through the concept of frequency response is most important. (See Article 10 and Refs. 4, 9, 10, 11, and 12.)

10. FREQUENCY RESPONSE

If the input is oscillated sinusoidally at constant amplitude and frequency there will be a transient which dies out and then there will remain a steady-state response with the output, error, and all components also oscillating sinusoidally. The ratio of the amplitude of output oscillation to that of the input oscillation is a function of frequency and is called the *magnitude of the system transfer function*, denoted by the symbol M. Similarly the difference in phase of the two sinusoids is called the *phase of the system transfer function* and denoted by the symbol ϕ.

The magnitude and phase of the system transfer function are easily computed by the following steps illustrated by the simple example used for eq. 2.

1. Set up the differential equation for the system.

2. Replace d/dt by p, and $\int ( )dt$ by $1/p$:

$$Jp^2\theta_o + fp\theta_o = K_o(\theta_i - \theta_o)$$

3. Solve the equation for θ_o/θ_i. This is the *system transfer function in operational form.*
4. Replace p by $(j\omega)$ where $j = \sqrt{-1}$ and $\omega = 2\pi \times$ frequency.

$$\frac{\theta_o}{\theta_i} = \frac{K_o}{(K_o - \omega^2 J) + j\omega f} = \frac{R_N + jX_N}{R_D + jX_D} \tag{7}$$

where R and X denote numbers found from the constants of the system and the frequency, the subscripts standing for numerator and denominator.

This is the *system transfer function in frequency form.* It is a complex number with the magnitude M and phase angle ϕ. Thus

$$M = \left|\frac{\theta_o}{\theta_i}\right| = \frac{\sqrt{R_N^2 + X_N^2}}{\sqrt{R_D^2 + X_D^2}} \tag{8}$$

and

$$\phi = \angle\frac{\theta_o}{\theta_i} = \tan^{-1}\frac{X_N}{R_N} - \tan^{-1}\frac{X_D}{R_D} \tag{9}$$

Figure 4 shows M and ϕ plotted as functions of frequency for this servomechanism. Since they correspond to the same system as the transient responses of Fig. 2, they illustrate certain general interpretations that may be applied to the frequency response:

1. A large resonant peak for M corresponds to a poorly damped or oscillatory transient response. For good design, the peak value of M is usually limited to less than 1.5, although it is often better to keep M less than 1.25.
2. Large phase shift at low frequency corresponds to sluggish response.
3. The time and frequency scales vary inversely (see Figs. 2 and 4) so that a quick time response corresponds to a high-frequency response.
4. One way to specify the characteristics of a servomechanism without giving all details is to give the peak value of M and the frequency at which the phase ϕ is some specific value, say 45 degrees. Thus for $\zeta = 0.6$, the peak of M is 1.05 and ϕ is 45 degrees at $\omega = 0.55\ \omega_n$. With few exceptions, the fastest servomechanisms have the 45-degree phase-shift point below 20 radians per sec if M is under 1.5.

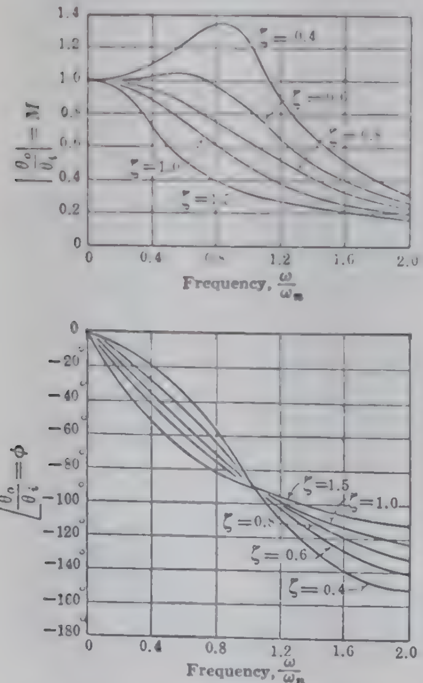


FIG. 4. Frequency response.

For purposes of synthesis, this means of calculation and interpretation is still not ideal since the effect on the system of each parameter is not easily visualized. The following methods, which have been derived from principles and theories originally applied to electrical feedback amplifiers, are superior.

These methods are based on the following algebraically true relation (Fig. 1):

$$\frac{\theta_i}{\theta_o} = \frac{\theta}{\theta_o} + 1 + \frac{\theta_f}{\theta_o} \tag{10}$$

Each output-to-input ratio is a transfer function and each input-to-output ratio is a reciprocal or *inverse transfer function* of some part of the system. Thus θ/θ_o is the inverse transfer function of the forward path of the closed loop and $(1 + \theta_f/\theta_o)$ is the transfer function of the return or feedback path.

Since these transfer functions, when in frequency form, have a magnitude and phase angle (or a real and imaginary component) they may be plotted at each frequency as a complex number vector from the coordinate origin. As frequency varies, the vector extremity plots out a locus. Thus a transfer function or its inverse may be plotted as a single curve, such as those in Fig. 5, with the numbers along the curve showing the frequency at each point.

In addition to being plotted as vectors, transfer functions have similar mathematical properties. If a number of networks and devices are placed in series, with the input of each fed by the output of the preceding unit, the magnitude of the overall transfer function is equal to the product of all the individual magnitudes. Also, the total phase shift is the sum of the individual phase shifts. These are the same as the properties of two-dimensional vectors used in plotting complex numbers. Similarly, two units in parallel call for vector addition of transfer functions. This property makes it easy to calculate transfer functions and to separate out the effect of each component, particularly in the case of θ/θ_o and θ_f/θ_o which usually consist of many elements in series.

Curve A of Fig. 5 shows such a locus for θ/θ_o. If there is no feedback θ_f, it is apparent that θ_i/θ_o is represented by the same plot if a new origin is taken at -1. Thus the amplitude ratio M is measured as the reciprocal of the distance from the -1 point to the locus. The phase at any frequency is the angle of the locus point measured from the real axis about the -1 point. Thus, in order to keep the resonance peak low, the θ/θ_o locus must be kept away from the -1 point (Refs. 9 and 10).

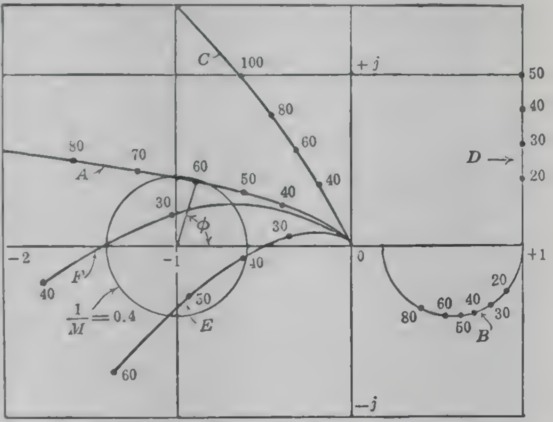

FIG. 5. Transfer functions plotted as the loci of vector extremities.

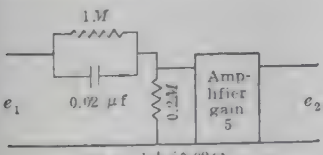
The following example illustrates the use of such a locus. Consider a servomotor with an inertia $J = 0.005$ in.-oz per radian per sec² and a speed-torque characteristic with $f = 0.125$ in.-oz per radian per sec. A 10-in.-oz dry friction load and a static error specification of $\frac{1}{2}$ radian sets the sensitivity K_o at 20 in.-oz per radian (see statement preceding eq. 2). Since $\theta/\theta_o = (\theta_i - \theta_o)/\theta_o = (\theta_i/\theta_o) - 1$, substituting in eq. 7 gives $\theta/\theta_o = -0.00025\omega^2 + j0.00625\omega$. This equation is plotted as curve A in Fig. 5. This locus approaches within 0.4 unit of the -1 point, showing a resonance value of $M = 2.5$.

To remove this resonance, a *lead network* such as is shown in Fig. 6 may be placed in the amplifier. Curve B of Fig. 5 plots its inverse transfer function (e_1/e_2), and, when the corresponding vectors of curves A and B are multiplied, curve C results. This circuit is called a lead network because its transfer function produces leading phase angles. It approximates a true derivative for low frequencies. In this example, the introduction of the lead network has reduced $M_{\max}$ to about 1.14 at $\omega = 50$ radians per sec, the minimum distance from the -1 point to the curve C being 0.88 unit.



$$\frac{e_2}{e_1} = \frac{1 + j0.02\omega}{1 + j0.004\omega}$$

FIG. 6. Lead network.

Thus far only lead networks in the forward loop have been used to deform the locus away from the -1 point. As an alternative, feedback signals contributing to the θ_f term can do the same thing. For example, if the output speed were fed back so that $\theta_f/\theta_o = K_f j\omega$, the locus would be raised vertically and away from the -1 point. This is one form of an *output feedback or control.*

Instability is easily spotted on these diagrams; it occurs if the locus moves past the -1 point in the clockwise direction as illustrated by curve E, Fig. 5. This transfer function is the result of adding to curve A a motor delay due to field inductance with a 0.02-second time constant, having an inverse transfer function $1 + j0.02\omega$ as shown by curve D. This unstable system can be made stable by decreasing K_o and thereby expanding the locus to curve F. The motor delays often determine the ultimate limit to the possible increase of K_o.

Such stability criteria, attributed to Nyquist, may be proved and rigorously stated by use of the Cauchy theorem (Refs. 13, 14, 15, and 16) concerning the number of poles and zeros of an analytic function within a contour.

These same concepts are used with other types of plots which have advantages under some circumstances. With these other methods θ_f is considered only as a local feedback which modifies θ_o/θ, and the overall feedback as just the return of θ_o to the differential device. The basic equation uses transfer functions only:

$$\frac{\theta_o}{\theta_i} = \frac{\dfrac{\theta_o}{\theta}}{1 + \dfrac{\theta_o}{\theta}} \tag{11}$$

One method plots θ_o/θ in the vector locus form and makes use of loci of constant M and ϕ on the same coordinates to determine θ_o/θ_i. This method is generally used only when $\theta_f = 0$, and its only advantage is that it deals with transfer functions rather than their inverses.

A second method (Refs. 14, 15, 17) plots $20 \log_{10} |\theta_o/\theta|$, or "gain" in decibels, against $\log \omega$ on rectangular coordinates. Bode has shown that the phase and magnitude curves are related so that stability can be assured by giving the magnitude alone a proper shape. A logarithmic scale is used so that component transfer functions in series may be added, rather than multiplied, thereby simplifying calculations.

Instead of determining the peak value for M, it is sometimes easier to specify merely the phase and gain margins for θ_o/θ. The phase margin is the angle of θ_o/θ when $|\theta_o/\theta| = 1$, it being good practice to have this between 40 and 60 degrees. The gain margin is the magnitude of θ_o/θ when the angle is 180 degrees, it being good practice to make this over 2 or 3. These margins determine how much parameters may change before instability results, but they usually limit the peak value of M at the same time.

DESIGN PROCEDURE. In the actual design of a servomechanism, it is necessary first to set down specifications concerning static error, speed lag, errors due to accelerations, load errors, maximum velocity of output, maximum acceleration of output, load forces, and inertia.

On the basis of these specifications the servomotor can be chosen which satisfies the torque, speed, and acceleration requirements. In addition, it must have sufficiently small response delays to allow the design of a nonoscillatory system.

The final step is the design of amplifiers and stabilizing and feedback circuits to give the desired frequency response and still meet the error specifications.

INDUSTRIAL ELECTRONIC CONTROL *

By L. W. HERCHENROEDER

Electronics is the science of conduction of electricity through a gas or vacuum. Industrial electronic equipment finds its place in those applications where it can do a better job than other equipment and in the many applications where no other equipment is available for doing the job. Electronic equipment, long the foundation of the communications industry, has become an accepted part of the large family of general industrial equipment.

11. ELECTRONIC TUBES

Tubes are the heart of electronic control. An electronic tube consists of a glass or metal envelope containing a gas or vacuum and having two or more elements. A two-element tube has a *cathode* and an *anode*. The cathode provides a source of electrons and, when the anode is at a positive potential with respect to the cathode, the electrons are attracted to the anode. Since the cathode is capable of releasing electrons into the space within the tube, a flow of electrons from the cathode to the anode results when the anode is positive. If the cathode is made positive and the anode negative, there is no continuous flow of electrons from the anode to the cathode because the anode does not supply electrons to the space in the tube. Thus the electronic tube is a rectifier because it permits flow of electrons in one direction only. The conventional direction of current flow is from positive to negative, which is opposite to the actual flow of electrons. When a tube is conducting, the current flows, in the conventional sense, from the anode to the cathode.

The cathode is caused to emit electrons by various means. The most important is *thermionic emission*, in which electrons are aided in their escape from the cathode by heating the cathode material. In some tubes the filament is used as the cathode; in others the cathode is indirectly heated by the filament. Some tubes have cold cathodes, and electrons are forced to leave the cathode by a high voltage gradient. Phototubes utilize photoelectric emission. Photosensitive materials on the cathode emit electrons upon exposure to light.

Tubes may be broadly classified as *vacuum* tubes and *gas* tubes. Vacuum tubes are characterized by low current-carrying capacity and high internal voltage drop while gas tubes are characterized by high current-carrying capacity and low internal voltage drop. The vacuum tube is capable of high amplification with a fine degree of control while the gas tube is relatively coarse in its action. Thus the vacuum tube finds use as a regulating or controlling element while the gas-filled tube does the heavy work. Vacuum and gas tubes take many forms. The tubes most widely used in industrial control are kenotrons, phototrons, phanotrons, thyratrons, ignitrons, and phototubes.

KENOTRONS, often called **diodes,** are two-element vacuum tubes with hot cathodes, used mainly as rectifiers to supply relatively small currents. They are capable of supplying as high as 100,000 volts for electrostatic dust precipitation, x-ray, and radio.

Kenotrons have a high internal voltage drop determined to a large extent by the space charge, which is caused by the cloud of electrons in the space between the cathode and anode. The charge due to the free electrons alters the potential distribution between the anode and cathode so that the potential near the cathode may actually be more negative than the cathode. Electrons being emitted are then repelled, and those emitted at the lower velocities will be forced to return to the cathode. Under these conditions the current is said to be space-charge-limited.

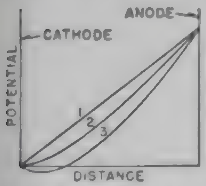

FIG. 1. Potential distribution in a kenotron.

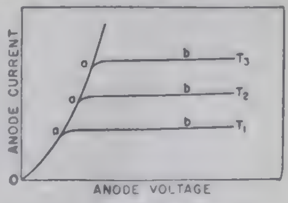

FIG. 2. Typical kenotron characteristic for several filament temperatures.

Figure 1 shows the change in potential distribution in the tube as the cathode emission is changed. On curve 1 the cathode is cold, there is no emission of electrons, and the potential distribution is a straight line. On curve 2 the cathode is heated, some emission is obtained, and the effect of space charge lowering the potential near the cathode is shown. Emission is increased further for curve 3 and results in a negative potential near the cathode. Electrons emitted from the cathode are at first repelled by the field and only those emitted with more than a certain velocity can pass through the negative field and be accelerated toward the anode. Electrons emitted with less velocity are repelled and return to the cathode.

---

* In preparing this chapter the author has consulted the first two references at the end of the chapter (p. 17-37) for much of the basic information presented.

Figure 2 shows a typical kenotron voltage-current characteristic for several filament temperatures. From *O* to *a* on the various curves, the anode current is limited by the space-charge effect. From *a* to *b* the anode current is limited by the number of electrons the cathode can emit. The anode current varies approximately as the 1.5 power of the anode voltage over the range where the space-charge effect predominates.

GAS-FILLED TUBES have considerably different characteristics. Electrons passing from the cathode to the anode collide with gas particles and tear away electrons, thus making the gas particles positively charged ions. The positive ions are attracted toward the cathode; however, since they have much greater mass than electrons, their speed is much slower. While traveling toward the cathode, the positive ions neutralize the charge of many of the fast-moving electrons, thus neutralizing the negative space charge.

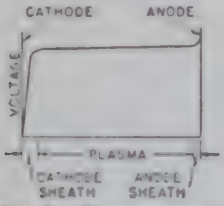

Fig. 3. Phanotron voltage distribution.

Figure 3 shows that very little voltage drop occurs in the plasma, which fills most of the space between cathode and anode, or in the anode sheath, a thin layer near the anode. Most of the voltage drop occurs in the cathode sheath, a thin layer near the cathode. The drop across a gas-filled tube is of the order of 15 volts and is practically constant over the normal range of load current.

PHANOTRONS are two-element gas-filled tubes used mainly as rectifiers for voltages up to approximately 20,000 and medium currents. They have hot cathodes and are usually filled with mercury vapor. In starting up phanotron rectifiers, the application of anode voltage must be delayed until the cathode comes up to normal temperature in order to prevent destruction of the cathode by positive-ion bombardment. Rectigons and tungars are low-voltage gas-filled tubes used for charging batteries. They have hot cathodes and are usually filled with argon gas.

PLIOTRONS are vacuum tubes with hot cathodes and having three or more elements. There are many varieties of pliotrons; those having three elements are called triodes; those with four elements, tetrodes, and those with five elements, pentodes. Amplification, the characteristic that has made the pliotron so useful, can best be described by considering the triode.

TRIODES are merely kenotrons with the addition of a third element called the grid. The grid is a conductor inserted between the cathode and anode. Usually it is a helix of wire concentric with the cathode. A given change in the input to the grid of a triode will result in a much greater change in the anode circuit, which results in amplification.

The grid controls the anode current by its effect on the space charge. The anode current of a triode is limited by the space-charge effect. Enough anode current will flow to produce a space charge that will result in a slight negative potential near the cathode similar to that shown for a kenotron in Fig. 1, curve 3. By varying the grid voltage, the potential distribution, neglecting the space charge, can be varied, thus varying the anode current required to produce the space charge necessary to give a slight negative potential near the cathode.

The grid is normally operated at a negative potential. Electrons, therefore, are not attracted to the grid so that grid current and input power to the tube are negligible.

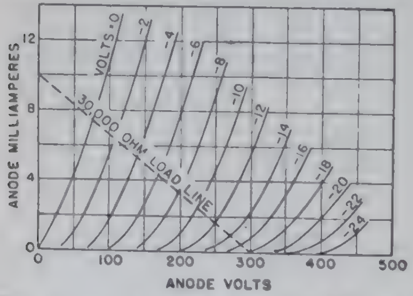

Fig. 4. Anode characteristic for a triode with 30,000-ohm load line.

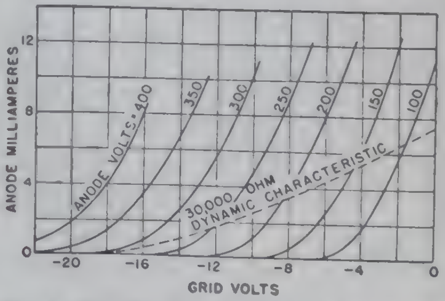

Fig. 5. Transfer characteristic for a triode with 30,000-ohm dynamic transfer characteristic.

Figure 4 shows the *anode characteristic* of a typical triode in which anode current is plotted against anode voltage for various values of grid voltage. The *transfer characteristic*, in which anode current is plotted against grid voltage for various values of anode voltage, is shown in Fig. 5. The data on the two sets of curves are identical; they are merely plotted in different ways.

Several coefficients or "constants" descriptive of the performance of a tube may be obtained from Figs. 4 and 5. The *amplification factor* μ is the rate of change of anode voltage for a change in grid voltage, with the anode current being constant. For example, in Fig. 4, at 4-ma anode current and -6-volt grid voltage, the anode voltage is 165. At 4 ma and -4-volt grid voltage, the anode voltage is 125. Therefore,

$$\text{Amplification factor} = \mu = \frac{\text{Change in anode voltage}}{\text{Change in grid voltage}} = \frac{165 - 125}{6 - 4} = 20$$

Anode resistance is the rate of change of anode voltage with respect to anode current, the grid voltage being constant. In Fig. 4 for a grid voltage of -6 volt and 6-ma anode current, the anode voltage is 185. At 4 ma the anode voltage is 165. Therefore,

$$\text{Anode resistance} = R_A = \frac{\text{Change in anode voltage}}{\text{Change in anode current}} = \frac{185 - 165}{0.006 - 0.004} = 10{,}000 \text{ ohms}$$

Mutual conductance is the rate of change of anode current with respect to grid voltage, the anode voltage being constant. In Fig. 4 for anode voltage of 150 and -4 grid volts, the anode current is 6.6 ma. For -6 volts the anode current is 2.6 ma.

$$\text{Mutual conductance} = G_M = \frac{\text{Change in anode current}}{\text{Change in grid voltage}} = \frac{0.0066 - 0.0026}{6 - 4} = 0.002 \text{ mho}$$

The above calculations are only approximate as small increments of voltage and current should be taken for accurate results. To be theoretically correct, the increments should be infinitesimal in magnitude. Amplification factor, anode resistance, and mutual conductance have the following relationship:

$$\mu = R_A G_M$$

Thus, if any two are known, the third may be found. Figure 6 shows a plot of the three functions against anode current. It will be noted that the amplification factor is practically constant and that the anode resistance and mutual conductance vary considerably.

The curves in Fig. 5 are plotted for constant values of anode voltage. In practice a load resistance will be connected in series with the anode and the constant voltage supply. When the grid voltage is changed, the anode current is changed, and the anode voltage must change due to the change in drop across the load resistor.

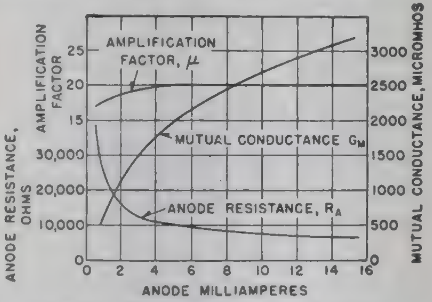

Fig. 6. Tube parameters for a triode.

To take account of the change in anode voltage, the *dynamic transfer characteristic* should be constructed. Assume that the anode supply is 300 volts and the load resistance 30,000 ohms. If the anode current is zero, the entire 300 volts will appear at the anode. If all the voltage is across the resistor, the anode current will be 10 ma and the anode voltage zero. Plot these two points on the anode characteristic and join them with a straight line, as shown by the dotted line in Fig. 4. It is known as the *load line*. Pick off the intersections of the load line with the anode characteristic curves and plot them on the transfer characteristic as shown by the dotted line in Fig. 5. The dotted line of Fig. 5 is called the dynamic transfer characteristic. It applies only for a load resistance of 30,000 ohms and an anode supply of 300 volts.

TETRODES are four-element vacuum tubes having a cathode, control grid, screen grid, and anode. They are the equivalent of a triode with an extra grid, called a screen grid, located between the control grid and the anode. The screen grid improves the performance of the tube by reducing the effect of the change in anode voltage on the cathode space charge and by shielding the grid from the anode, thus reducing the capacitance between the grid and anode. A positive potential is applied to the screen grid, and, since it is nearer the cathode, the screen grid has much greater control over the potential distribution near the cathode than does the anode.

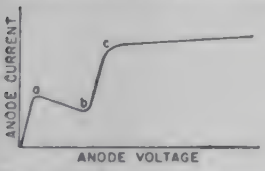

Fig. 7. Anode characteristic for a tetrode.

Figure 7 shows the anode characteristic of a typical tetrode and shows that the anode current is practically independent of anode voltage in the normal operating range to the right of point *c*. The peculiar characteristic to the left of *c* is due to the anode being less positive than the screen grid. When electrons arrive at the anode with greater than a certain velocity, electrons are emitted from the anode. This phenomenon, called *secondary emission*, occurs in all tubes. In a triode the anode is the only positive element, and the electrons due to secondary emission are attracted back to the anode. When the screen grid in a tetrode is more positive than the anode these electrons are attracted to the screen grid. The result is distortion or unstable operation when the anode voltage is less than the screen-grid voltage.

Tetrodes provide much higher amplification than triodes; however, they have become practically obsolete because of the superior characteristics of pentodes.

PENTODES are five-element vacuum tubes containing cathode, anode, and three grids. Essentially the pentode is a tetrode with an additional grid, called the suppressor grid, between the screen grid and the anode. The purpose of the suppressor grid is to prevent the undesirable operating characteristics of the tetrode for anode voltages less than the screen-grid voltage. The suppressor grid is usually connected to the cathode and, therefore, produces a low potential near the anode. Electrons released from the anode by secondary emission find themselves in a space in which the anode is the most positive element, and they return to the anode. The anode voltage can, therefore, swing below the screen-grid voltage without obtaining adverse tube characteristics. Figure 8, which is a typical pentode anode characteristic, shows that the anode current is practically independent of anode voltage.

VARIABLE-MU TUBES have high amplification for small negative-grid voltages and low amplification for high negative-grid voltages. Figure 9 is the anode characteristic of a typical variable-mu pentode. Variable-mu tubes are also called *supercontrol* or *remote-cut-off* tubes as contrasted to *sharp-cut-off* tubes illustrated by Fig. 8. Cut-off refers to the value of grid voltage that reduces the anode current to zero.

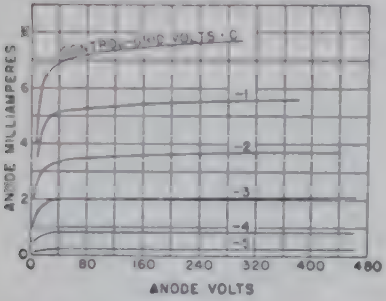

FIG. 8. Anode characteristic for a conventional pentode.

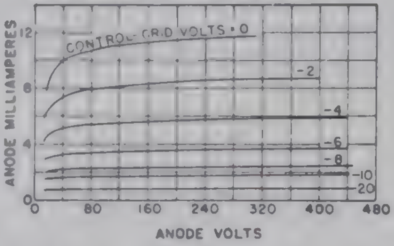

FIG. 9. Anode characteristic for a variable-mu or remote cut-off pentode.

BEAM POWER TUBES are tetrodes having characteristics similar to pentodes. Electrodes at cathode potential focus the electron stream in a beam directed at the anode. Near the anode a zone is created having a concentration of electrons sufficient to create a potential less positive than the anode. The zone of concentration of electrons has properties similar to the suppressor grid in a pentode. Thus electrons due to secondary emission of the anode are attracted back to the anode. Beam tubes are ordinarily used as power-output tubes, and pentodes are used as voltage amplifiers and for low power output.

THYRATRONS are hot-cathode gas-filled tubes having one or more grids. Thus a three-element thyratron is a phanotron with the addition of a control grid. The action of the control grid in a thyratron is quite different from that of the grid in a pliotron. The control grid of a pliotron has control of the anode current at all times. The control grid of a thyratron has only a triggering action. It can prevent the tube from conducting but once it initiates an anode current, the grid loses control. The anode current can then be stopped only by reducing the anode voltage below the arc drop in the tube, either by opening the anode circuit with a switch or by otherwise reducing the anode voltage to a value below the arc drop. In practice, thyratrons are usually operated with an alternating anode voltage. The anode voltage becomes zero every half cycle, at which time the grid regains control of the tube. For most industrial applications the grid, therefore, gains control of the anode current often enough to give the equivalent of continuous control.

The action of the control grid can be explained as follows. As long as the tube is not conducting, the control grid can be maintained at a potential that will prevent flow of electrons from the cathode to the anode. If the grid voltage is made less negative or more positive, a point is reached (called the firing point) where sufficient electrons are emitted from the cathode to cause ionization of the gas in the tube. The positive ions thus formed permit the flow of large currents through the tube with a low voltage drop, as was described for the phanotron. Positive ions form a sheath around the grid, giving it a positive potential and rendering it ineffective in controlling the anode current. Figure 10 shows the firing characteristics of a mercury vapor thyratron. The shaded area shows the variation in firing point that may be expected because of temperature and other variations that occur over the life of the tube.

The addition of a shield grid to the three-element thyratron improves the operating characteristics in several ways. The shield grid almost surrounds and isolates the cathode, anode, and control grid. The capacity between the anode and control grid is minimized, thus reducing the chance of loss of control due to transients in the anode circuit. The control-grid current is reduced, and the firing characteristics can be modified by adjusting the potential on the shield grid. Two signals can be used to control the tube—one operating the control grid and the other the shield grid.

When thyratrons are used in a-c circuits, the average anode current can be controlled by controlling the angle at which the tube is fired. Figure 11 illustrates one method by which this can be accomplished. An alternating voltage is applied to the control grid, and some means of shifting the phase of the grid voltage with respect to the anode voltage is provided. The tube will fire at the point of intersection of the grid voltage with the firing voltage characteristic. Figure 11*A* shows the grid voltage in phase with the anode voltage, resulting in flow of anode current over most of the positive half cycle. Figure 11*B* shows the grid voltage shifted so that the firing of the tube is delayed almost 90 degrees, and anode current flows over slightly more than half the positive half cycle of the anode voltage. There are several other means of controlling the firing angle. One involves permanently shifting the grid voltage 90 degrees and adding a d-c component to shift the a-c wave up and down to vary the point of intersection with the firing voltage characteristic. Another method involves applying a sharp pulse of voltage to the control grid every half cycle and providing means of shifting the phase of the pulse to control the firing point.

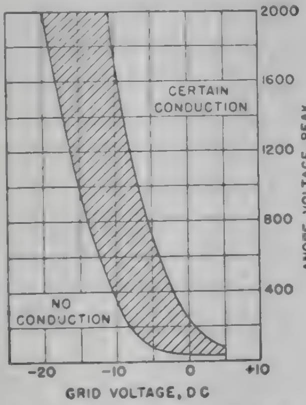

Fig. 10. Firing characteristic for a mercury vapor thyratron.

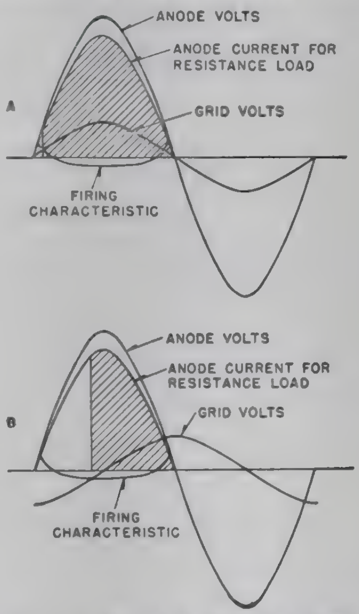

Fig. 11. Control of firing of a thyratron by shifting the phase angle of the grid voltage.

IGNITRONS are mercury pool cathode tubes containing an element called an ignitor. The function of the ignitor is similar to that of the grid in a thyratron, i.e., it controls the initiation of flow of current in the tube but has no control once the anode current is flowing. The cathode of an ignitron consists of a pool of mercury in the bottom of the tube. The tip of the ignitor electrode projects into the mercury pool. Passing current through the ignitor causes an arc to form between the ingitor and mercury pool. If the anode voltage is sufficiently positive, the arc will spread to the anode and the tube will continue to conduct as long as the anode voltage remains sufficiently positive to maintain the arc. Thus, by supplying a pulse of current to the ignitor at the proper time, the tube can be caused to conduct over the desired portion of a cycle in a manner similar to the control of conduction of a thyratron by means of the control grid.

Ignitrons are capable of carrying heavy currents because of the mercury pool cathode, which is capable of supplying an almost unlimited quantity of electrons once the arc has been established. Sealed-off tubes are available with average current-carrying capacities up to 400 amperes. Larger ratings are available in pumped-type tubes which are used for large-capacity rectifier substations.

Ignitron tubes have metal walls and are provided with water jackets or cooling coils to remove the heat generated by the heavy current flowing in the tube. Tubes for rectifier or other continuous service are provided with a baffle and splash ring to protect the anode from mercury dispersed by agitation of the mercury pool. The larger tubes have an anode shield to shorten the de-ionization time of the tube.

Anode firing is a simple method of initiating conduction of an ignitron. A phanotron is connected between the anode and ignitor. When the anode voltage becomes sufficiently positive, the phanotron conducts current to the ignitor, causing the ignitron to conduct. The phanotron can be replaced by a thyratron, and, by controlling the control grid of the thyratron, conduction of the ignitron can be controlled.

More positive firing can be obtained by using a firing circuit separate from the anode circuit. One such circuit uses a rectifier to charge a capacitor, which discharges through a thyratron and the ignitor. By controlling the firing point of the thyratrons, the point on the voltage wave at which the ignitron fires can be controlled.

PHOTOELECTRIC DEVICES may be classified as photoemissive, photovoltaic, or photoconductive. Photoemissive devices operate on the principle that light or other radiation falling on certain materials causes electrons to be emitted. Photovoltaic devices produce voltage while the resistance of photoconductive devices changes upon exposure to radiation. Photoemissive and photovoltaic devices are used on most industrial applications.

Phototubes are diodes having a cathode with a photosensitive surface. The electrons emitted by the cathode depend on the cathode material and the wavelength and intensity of the radiation falling on the sensitized surface. Cathode photosensitive surfaces are made of a number of materials that are sensitive over different wavelength bands of radiant energy. Several surface designations are used as unofficial standards. The S_1 surface has maximum sensitivity in the red and infrared bands and is quite suitable for use with incandescent light sources. The S_2 surface has almost the same sensitivity characteristics as the S_1 surface and will probably be abandoned. Because the S_3 surface has a sensitivity range approximately that of the human eye it is desirable for colorimetry. The S_4 surface has maximum sensitivity in the ultraviolet and is very sensitive to sunlight and fluorescent or mercury-vapor light sources.

Sensitivity of phototubes is often expressed in microamperes of anode current per lumen of light. Since phototubes are sensitive to radiation outside the visible light band, a more scientific measure of sensitivity is the ratio of microamperes of anode current to microwatts of radiant energy for a definite wavelength band. For convenience, the sensitivity is often expressed as microamperes per lumen from a given light source.

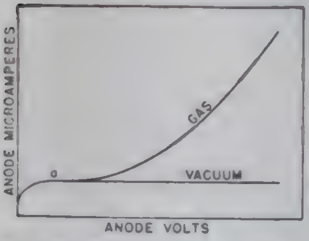

Fig. 12. Characteristics of vacuum and gas phototubes.

Phototubes may be of the vacuum or gas type. Figure 12 shows that, above *a*, the anode current remains constant with increasing anode voltage for the vacuum phototube. The anode current of the gas phototube increases with increasing anode voltage because of ionization of the gas. Because of its greater sensitivity the gas phototube is used on the majority of industrial applications.

In spite of its inferior sensitivity, the vacuum phototube has several advantages over the gas phototube that are important in some applications. The output of the vacuum phototube is much more stable than that of the gas phototube. The vacuum phototube output is a linear function of the illumination. The output of the gas phototube is not linear. The vacuum phototube has no measurable time lag in its operation. The gas phototube has a time lag in its response to illumination which results in a decrease of sensitivity for high-frequency illumination. The dynamic sensitivity of gas phototubes is substantially the same as the static sensitivity up to approximately 1000 cycles per sec; however, above 10,000 cycles per sec, the reduction in dynamic sensitivity may be serious. Gas phototubes are subject to destructive glow discharges if more than a certain anode voltage is used. Vacuum phototubes are not subject to this effect.

Conventional phototubes provide small output current even at high illumination. The multiplier phototube utilizes secondary emission to amplify greatly the weak photoelectric current. The tube consists of a photosensitive cathode, an anode, and a series of elements (usually nine) called dynodes. Electrons emitted by the cathode are focused on the first dynode, where an amplified number of electrons are emitted by secondary emission. These electrons are focused on the second dynode, where secondary emission also occurs, resulting in further amplification. The electrons are focused from dynode to dynode, secondary emission and amplification occurring at each step, and are finally collected by the anode greatly amplified in number over the electrons originally emitted from the cathode.

Photovoltaic cells differ from phototubes in that they generate a voltage when exposed to illumination. Their output is high enough to operate an indicating instrument. The principal application of photovoltaic cells is for photographic exposure meters and for illumination studies.

12. RECTIFIERS

Rectifiers are used to convert a-c power to d-c power. The amount of power converted may vary from less than a watt to thousands of kilowatts. Since the electronic tube allows flow of current in one direction only, it is much used in rectifying circuits.

Rectifier circuits vary considerably, depending on the amount of power required and the type of load. Table 1 shows several common rectifier circuits used for small- and medium-power output. The simplest is the single-phase half-wave rectifier consisting of a transformer and a single diode tube in series with the load. The tube permits current to flow during the half cycle when the anode is positive and prevents current flow during the half cycle when the anode is negative. The result is a pulsating unidirectional output voltage and current. The unidirectional current also flows in the transformer and tends to saturate the core. This must be taken into account in the design of the transformer and results in a more expensive transformer. The pulsating output voltage can be smoothed by use of a suitable filter; however, the single-phase half-wave rectifier is usually limited to small-power outputs.

The single-phase full-wave rectifier consists of two tubes and a transformer with a center-tapped secondary as shown in Table 1. When the anode of one tube is positive, the other anode is negative, and vice versa. One tube conducts current for one half of the cycle, and the other tube conducts the other half of the cycle. The current through the load is in the same direction regardless of which tube is conducting. The wave shape is much more continuous than that of the single-phase half-wave rectifier, and, since current is conducted for both halves of the cycle, saturation of the transformer does not occur. A variation of this circuit, replacing the two tubes by a single tube having two anodes and a common cathode, is widely used to supply d-c power in electronic equipment.

The single-phase full-wave bridge circuit consists of a transformer and four tubes as shown in Table 1. Tubes *A* and *D* conduct over half the cycle, and tubes *B* and *C* conduct over the other half of the cycle. The wave shape of the output is the same as the full-

Table 1. Rectifier Circuits and Characteristics

	Single Phase			3 Phase Zigzag
	Half Wave	Full Wave	Full-wave Bridge	
Circuit				Output Voltage Wave Shape				Average d-c volts	1.00	1.00	1.00	1.00
Peak d-c volts	3.14	1.57	1.57	1.21
Peak inverse volts	3.14	3.14	1.57	2.09
Anode current per tube				
Average	1.00	0.50	0.50	0.33
Peak (resistance load)	3.14	1.57	1.57	1.21
Peak (inductance load)		1.00	1.00	1.00
Transformer				
Rms sec volts/leg	2.22	1.11	1.11	0.854
Secondary volt-ampere	3.49	1.57	1.11	1.71
Primary volt-ampere	3.49	1.11	1.11	1.21
Ripple				
Major frequency	*f*	2*f*	2*f*	3*f*
Major voltage rms	1.11	0.472	0.472	0.177

wave center-tap rectifier. The full-wave bridge has the advantage of using a conventional transformer; however, four tubes are required. The full-wave bridge circuit is used extensively with metallic rectifiers of the copper oxide or selenium type as there is no disadvantage in building them in four legs.

The three-phase half-wave zigzag circuit requires three tubes, each conducting over one-third the cycle. The output is more smooth than that of the single-phase rectifiers. The zigzag connection of the transformer secondary avoids saturation of the core. Many other rectifier circuits are used, depending on the application. Most rectifiers for large-power outputs use six- or twelve-phase circuits.

13. AMPLIFIERS

Amplification is probably the most useful property of the electronic tube. Input signals to electronic devices are often minute and must be amplified many times to perform the desired task. Figure 13 shows a typical single-stage amplifier circuit using a triode. An input voltage e_g in series with a grid bias voltage E_{cc} is applied between the grid and cathode. Anode supply voltage E_{bb} is connected between the anode and cathode in series with the load resistor R_L. The heater supply is not shown. Amplification of an alternating input voltage is illustrated in Fig. 14. The dynamic transfer characteristic of Fig. 5 is used with 30,000 ohms load resistance, 300 volts anode supply, and 8 volts grid bias. The anode current can be obtained by projecting the input voltage on the dynamic transfer characteristic. The output curve may also be used to give the load voltage by using the scale to the right, since the load voltage is equal to the anode current multiplied by the load resistance. The amplification may be obtained by comparing the alternating component of the load voltage with the input voltage. The total input change is 12 volts, compared to a total output change of 160 volts, resulting in amplification of 13.3.

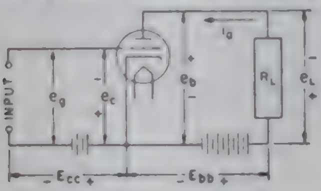

FIG. 13. Single stage amplifier.

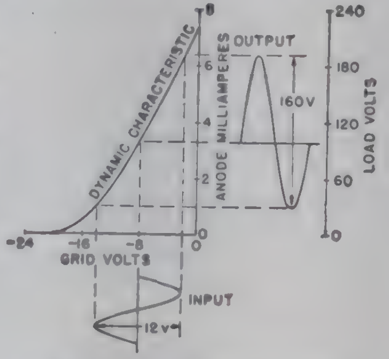

FIG. 14. Class *A* amplification.

AMPLIFIERS are divided into several classifications, depending on the portion of the cycle during which anode current is allowed to flow. Class *A* amplifiers have a grid bias and alternating grid voltage such that anode current flows over the entire cycle, as shown in Fig. 14. Class *AB* amplifiers have a grid bias and alternating grid voltage such that anode current flows for more than half but less than the entire cycle. Class *B* amplifiers have the grid biased to cut-off so that anode current flows over half of each cycle, as shown in Fig. 15. Class *C* amplifiers have the grid biased beyond cut-off so that anode current flows for less than half of each cycle. The subscript 1 may be used to indicate that no appreciable grid current flows during any part of the cycle, and the subscript 2 may be used to indicate that appreciable grid current flows during a portion of the cycle. Practically, the subscript 1 indicates that the grid is negative over the entire cycle, and 2 indicates that the grid is positive during a portion of the cycle.

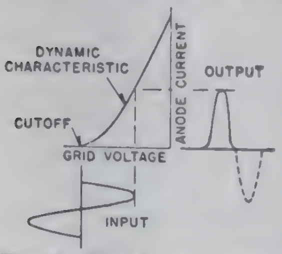

FIG. 15. Class *B* amplification.

Class *A* amplifiers reproduce the shape of the input signal with the least distortion; however, they have the poorest efficiency of the various classes. Class *AB*, *B*, and *C* amplifiers have, in the order named, higher efficiency and greater distortion of the input signal. For communication applications Class *AB* and Class *B* amplifiers are used in push-pull circuits to reduce distortion. Distortion is often of little importance in industrial applications, and Class *B* or Class *C* operation may be used. In many cases an alternating anode and grid bias voltage are used so that anode current flows only when the anode is positive and the grid voltage is above cut-off. Photoelectric circuits are often operated in this manner.

Amplifiers may also be classified as voltage or power amplifiers. The difference is a matter of design emphasis. Amplifiers usually have several stages in cascade, the last of which is a power amplifier and all the rest of which are voltage amplifiers. The circuit elements of a voltage amplifier are selected to amplify the voltage of the signal with little regard for the power output. Tubes with high amplification factor and low anode current capacity are used. The power amplifier is used to supply some device requiring a relatively large amount of power, such as a relay or the field of a generator or motor. Power-output tubes are designed to provide a certain power output with little regard being given to amplification of voltage.

Direct-coupled Amplifiers. Many circuits have been devised for coupling successive stages of cascaded amplifiers, a few of which will be described. The simplest is the direct-coupled amplifier, shown in Fig. 16. The input is amplified by tube T_1 and appears across resistor R_{L1}. The grid of T_2 is connected to the anode of T_1 through the battery E_{cc2}. The grid circuit of T_2 includes the anode supply E_{bb1} of T_1 and a high-voltage bias E_{cc2} is required to bring the grid voltage down to the normal operating range. The direct-coupled amplifier is extensively used for the amplification of d-c and low-frequency a-c signals; however, it has several disadvantages. The power supply is considerably more involved and expensive than it is for other types of coupling. A serious disadvantage is the tendency to drift with changing tube characteristics and changes in power-supply voltage. Many elaborate circuits have been devised to counteract the drift of the simple direct-coupled amplifier.*

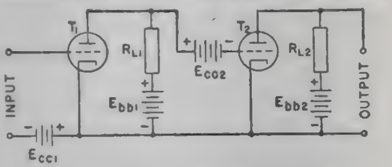

FIG. 16. Direct-coupled amplifier.

Resistance-capacitance-coupled amplifiers (often called resistance-coupled amplifiers) are widely used in electronic circuits for the amplification of alternating voltages. Figure 17 shows the connections between successive stages. The alternating input is amplified by tube T_1 and appears across resistor R_{L1} along with a d-c component as shown in Fig. 14. The alternating component of this voltage causes an alternating current to flow through the capacitor C and the grid resistor R_{g2}. An alternating voltage thus appears across R_{g2} and serves as the input to the tube T_2. The capacitor C blocks the d-c anode supply of T_1 from the grid of T_2, and a common anode supply can be used on all tubes. The amplification of the resistance-capacitance-coupled amplifier can be made fairly constant for intermediate frequencies (roughly 100 to 10,000 cycles per sec). At lower frequencies the amplification drops off because of the increased impedance of capacitor C, and at higher frequencies the amplification drops off because of the internal capacitance of the tube elements.

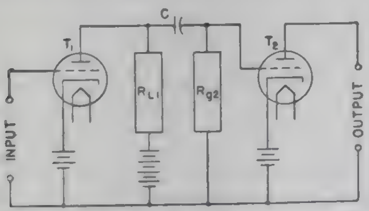

FIG. 17. Resistance-capacitance-coupled amplifier.

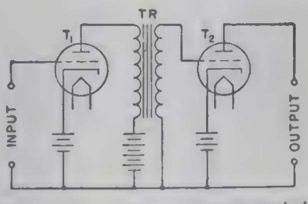

FIG. 18. Transformer-coupled amplifier.

Transformer-coupled amplifiers may be used for amplifying alternating voltages. Figure 18 shows the primary of a transformer connected in the anode circuit of tube T_1. The secondary of the transformer is connected in the grid circuit of tube T_2. Alternating components of the output of tube T_1 are coupled to the grid of T_2, while the d-c component is not. Transformer coupling has the advantage of introducing a lower d-c drop in the anode circuit than resistance coupling. Also, the voltage amplification can be increased approximately in proportion to the turns ratio of the secondary to primary. The transformer becomes expensive, however, if good frequency response is required, and transformer coupling is little used for voltage amplifiers.

Push-pull amplifiers are often used in power output stages in order to obtain high output power with low distortion. A push-pull circuit with transformer input and output is shown in Fig. 19. The input transformer TR_1 has a center-tapped secondary and applies a grid voltage on T_1 that is 180 degrees out of phase with the grid voltage on T_2. Thus the grid of T_1 is at maximum voltage when the grid of T_2 is at minimum voltage. The primary of the output transformer TR_2 has a center tap to which the anode supply voltage is connected. The effect of the d-c component of the anode currents of the two tubes will cancel in the transformer since they flow in opposite directions in the primary. The fundamental frequency components of the anode currents will add since they are 180 degrees out of phase with respect to the center tap but flow in opposite directions in the winding. The second harmonic is most important from the standpoint of causing distortion and is canceled along with all other even harmonics generated in the tubes.

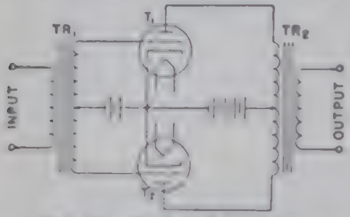

FIG. 19. Push-pull amplifier.

14. CONTROL APPLICATIONS

ELECTRONIC TIMING is widely used because of easy adjustment and accuracy of repetition of the timing interval. Most timing circuits are based on the time constant of a resistance-capacitance circuit, a typical example of which is shown in Fig. 20. The circuit is arranged to energize relay *CR* a certain time after switch *S* is closed. With *S* open, the grid of the thyratron functions as an anode in the circuit from line 1 through a portion of P_1, R_1, grid, cathode, and R_2 to line 2. The current flowing through this circuit causes a charge to build up on C_1 with the negative polarity on the grid side. When switch *S* is closed, the circuit to relay *CR* is completed through the thyratron, but the grid is negative because of the charge on C_1, and the tube does not fire. The grid voltage consists of an a-c component across a portion of P_1 and a d-c component across C_1. The capacitor C_1 discharges through R_1, and, when the voltage across C_1 becomes low enough, the a-c component of grid voltage will cause the tube to conduct and *CR* will pick up. The time interval may be adjusted by means of potentiometer P_1 which determines the voltage to which C_1 is charged when *S* is open.

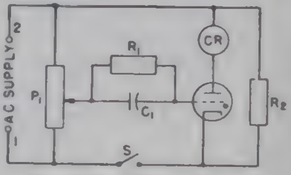

FIG. 20. Timing relay.

PHOTOELECTRIC RELAYS are available in several standard forms for general use in industry. Figure 21 shows the schematic diagram of a commercial photoelectric relay. It is relatively insensitive but is widely used when adequate illumination is available. The circuit is connected to energize the relay *CR* when the phototube is dark. The anode supply is alternating current for both the phototube and thyratron. The grid voltage controlling the firing of the thyratron is composed of the voltages across R_3 and R_2. An alternating voltage appears across R_3 that leads the thyratron anode voltage by approximately 90 degrees because of the phase shift circuit consisting of R_3 and capacitor C_2. The phototube conducts current only when its anode is positive. The capacitor C_1 is therefore charged by the phototube for half a cycle and discharges through resistor R_2 the other half cycle. The voltage across R_2 provides a negative bias on the thyratron grid, the value depending on the light falling on the phototube. When the light on the phototube is low, the voltage across R_2 is low, and the sum of the voltages across R_2 and R_3 is sufficient to cause the thyratron to conduct. When the light is bright, the voltage across R_2 is sufficiently high to reduce the grid voltage below that necessary to fire the thyratron. The coil of relay *CR* is in series with the anode circuit of the thyratron. Since current can flow only on the positive half cycle, the capacitor C_3 is used to prevent chatter of the relay. R_4 limits the charging current required of the thyratron. Potentiometer P_1 provides adjustment of the level of illumination at which the relay operates.

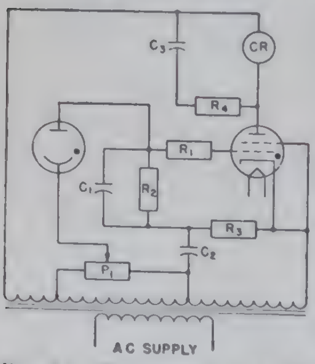

FIG. 21. Photoelectric relay using a-c anode supply.

The simple system described above, using an a-c anode supply, requires an illumination at the phototube of 40 to 50 foot-candles. Using a d-c anode supply for the phototube reduces the illumination requirement to 5 to 10 foot-candles. Adding a stage of d-c amplification between the phototube and thyratron reduces the requirements to 1 foot-candle or less. Making the system sensitive to rate of change of illumination (as described below) reduces the requirements to approximately 0.02 or 0.03 foot-candle.

Where background light is troublesome, a light source producing "chopped light" is desirable. A perforated disk is placed in front of the light source and driven by a synchronous motor, interrupting the light beam 540 times per sec. The amplifier circuit is made sensitive to the rate of change of light instead of the total change of light. Greater sensitivity is obtained and an a-c amplifier can be used. The "chopped light" system is of particular advantage where the light source is at a distance from the phototube or for outdoor applications where background illumination is difficult to eliminate.

The optical system is as much a part of the application as the photoelectric relay itself. The most common system is to direct the beam from the light source directly on the phototube. An example is automatic weight checking. The light source is placed on one side of the scale and the phototube on the other. When the weight is correct the scale pointer interrupts the light beam and operates the photoelectric relay.

A reflecting surface, either specular or diffuse, may be inserted in the light path. Diffuse reflection usually is preferred. Refraction of a liquid or solid is sometimes used. Radiation from a heated body is sometimes used to indicate temperatures above 1500 F.

There are several points to watch on photoelectric applications. The light source should be capable of giving sufficient illumination under the most unfavorable operating conditions, and the beam should cover as much of the phototube cathode as possible. The percentage and actual value of change in illumination on the phototube should be as high as possible with 50% change or more representing good practice. The optical system should be as short as possible, and extraneous phototube illumination should be kept to a minimum. Undue supply voltage fluctuation may require the use of a voltage-regulating transformer. Leads between the phototube and amplifier should be as short as possible to avoid picking up false signals. Preferably, the phototube should be mounted in the amplifier enclosure.

ELECTRONIC ADJUSTABLE-SPEED DRIVES are available in several standard forms. The electronic drives are comparable to the conventional adjustable voltage or Ward Leonard drives in which a motor-generator set provides adjustable voltage power to the armature of a d-c motor in order to obtain an adjustable-speed drive. The electronic motor control essentially substitutes a controlled thyratron rectifier for the motor-generator set; however, certain refinements such as speed regulation and current limit acceleration are included which are not as easily obtained with the motor-generator set drive.

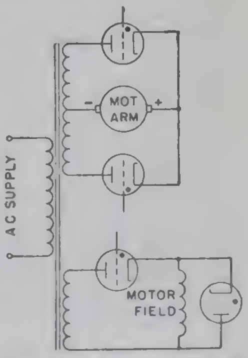

Fig. 22. Main power circuits for electronic motor control.

Figure 22 shows the main power circuits used in a typical electronic motor control. A single-phase full-wave rectifier supplies power for the armature of the d-c motor. By controlling the grids of the thyratrons, the voltage applied to the motor armature and, therefore, the speed of the motor, can be controlled. The motor field is supplied from a separate single-phase half-wave thyratron rectifier. A phanotron is used as a field-discharge tube which allows the current to flow through the highly inductive motor field during the half cycle that the thyratron is not conducting. Control of the thyratron grid results in control of the average motor-field current and provides adjustment of the motor speed by field weakening in addition to the speed adjustment by armature voltage control. When adjustment of speed by motor-field control is not desired, the thyratron may be replaced by a phanotron.

The speed of a d-c motor having constant-field current is essentially proportional to the armature voltage minus the voltage drop due to the resistance of the armature circuit. To maintain constant speed with change in motor load, the output voltage of the armature rectifier is regulated to equal a constant value plus the resistance drop in the motor. For applications requiring higher accuracy, a tachometer generator is coupled to the d-c motor, and the voltage output of the armature rectifier is regulated to maintain constant voltage output of the tachometer generator which results in constant motor speed.

Current-limit control is provided to protect the motor and tubes from excessive current and to provide smooth acceleration. A measure of current supplied to the motor armature is obtained by a current transformer or by other means. A regulating circuit is used that is inactive as long as the motor current is less than the desired amount. However, when the motor current attempts to exceed this amount, the grid circuit of the thyratrons is phased back to reduce the voltage output of the rectifier sufficiently to reduce the motor current to a safe value.

The motor can be reversed by means of contactors in the motor armature circuit. Control features such as dynamic braking and inching are provided by conventional means. Electronic control permits the use of small speed-control potentiometers that can be mounted in an ordinary pushbutton station.

CONTACTORS. The ignitron contactor consists of two ignitrons connected "back to back" as shown in Fig. 23. Each ignitron conducts on alternate half cycles, and alternating current flows through the load. The ignitrons have the function of an ordinary contactor, conducting current to the load when the relay contacts CR in the ignitor circuits are closed and preventing current flow when the relay contacts are open. The ignitron contactor can be operated frequently while it is handling large currents without the mechanical wear and burning of contacts associated with frequent operation of conventional magnetic contactors. Ignitron contactors have been used for motor control and show great promise where motors must be started frequently.

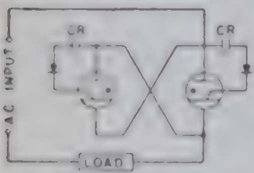

Fig. 23. Ignitron contactor.

Resistance welding has been the largest field for the ignitron contactor where it is used for controlling the primary current of a welding transformer. Resistance welding controls may be classified as nonsynchronous, synchronous precision, or energy storage.

Nonsynchronous control involves an ignitron contactor in the primary circuit of a welding transformer and an electronic timer to control the duration of the weld.

Synchronous precision control has several refinements which provide more uniform welds. Firing of the ignitron contactor is initiated at the natural power factor angle (the point on the voltage wave corresponding to zero current) of the welding transformer circuit. The polarity of the initial current wave is arranged to be opposite that of the last current wave of the preceding weld. Transient transformer currents are thus eliminated and each cycle of the current wave has a definite heating effect.

Heat control is obtained electronically by controlling the firing angle of the ignitrons. Firing the ignitrons at the natural power factor angle of the transformer circuit results in continuous flow of current and provides maximum heat in the weld. Increasing the delay of firing results in discontinuous current flow and reduces the heat in the weld.

Energy storage control is most frequently used on aluminum and its alloys and has the advantage of reducing current peaks taken from the line and providing consistent welds in spite of line voltage variations. Two systems are used, one storing the energy in the magnetic circuit of the welding transformer and the other storing the energy in capacitors. In the magnetic system an ignitron rectifier is connected to the primary of a special welding transformer and builds up flux in the transformer at a relatively slow rate. To make a weld, the primary circuit is opened and the decay of flux in the core causes a high current to flow in the transformer secondary.

In the capacitor system a rectifier is used to charge a bank of capacitors. The capacitors are connected to the welding transformer primary in series with an ignitron contactor. To make a weld, the capacitors are discharged through the primary of the welding transformer, thus inducing the welding current in the secondary. An auxiliary rectifier is used to reverse the transformer residual flux while the capacitors are being charged for the next weld. Both rectifiers are prevented from conducting during the weld cycle.

15. REGULATOR APPLICATIONS

REGULATION is a closed-cycle process as compared with control, which is an open-cycle process. The heating of a home with an ordinary furnace is an example of an open-cycle process. The amount of fuel and draft are set, and the furnace delivers enough heat to hold the house at the desired temperature under the existing conditions. If the outside temperature increases, the temperature in the house also increases because no information is sent back to the furnace to tell it that less heat is required to hold the desired temperature.

The addition of a thermostat and its associated equipment produces a closed cycle or regulating system. The thermostat measures the temperature in the room, compares it with the desired temperature, and causes the furnace to supply heat when the temperature is too low or shuts the furnace off when the temperature is too high. Variation in the outside temperature merely changes the percentage of time that the furnace is on.

Regulating systems comprise a reference quantity, a regulated quantity, an error detector that compares these two quantities and produces an error signal, and an amplifier that amplifies the error and causes an error corrector to operate on the regulated quantity so as to reduce the error. A block diagram of the elements of a regulating system is shown in Fig. 24. In the furnace regulator, the reference quantity is the desired temperature set on the thermostat, the regulated quantity is the temperature of the room, the error detector is the temperature-measuring bimetal in the thermostat, the amplifier consists of the thermostat contacts and relay and fuel-control device, and the error corrector is the furnace.

Regulating systems usually pose questions of stability and speed of response. Many regulating systems can be stabilized by reducing the amplification sufficiently; however, this remedy often defeats the purpose for which the regulator is desired. Antihunting and anticipating means are often used in regulating systems requiring high accuracy and speed of response. For a discussion of the general characteristics of regulating systems, see the chapter, "Automatic Regulators," in this Section.

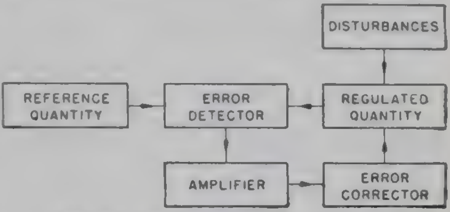

FIG. 24. Regulator block diagram.

Electronic equipment has several characteristics that make it highly desirable for use in regulating systems. High amplification can be obtained with negligible time delay. Because almost all other amplifiers have appreciable time delay, an electronic amplifier often simplifies the stability problem. Another advantage is the ease with which antihunting and anticipating circuits can be introduced and adjusted. The power input required by an electronic amplifier is very low. In many systems the power available for operating the regulator is so low that only electronic equipment can be used.

A TEMPERATURE REGULATOR for an electric furnace is shown in block diagram form in Fig. 25. The furnace is heated by resistor-type heaters connected to the power supply in series with a saturable reactor. The saturable reactor has a-c and d-c windings. When the current in the d-c winding is high, the reactor core is saturated, the reactance of the a-c winding is low, and maximum voltage appears across the furnace-heating elements, thus providing maximum heat input to the furnace. By decreasing the current in the d-c winding, the reactor core becomes less saturated, the reactance of the a-c winding increases, and less heat is delivered to the furnace.

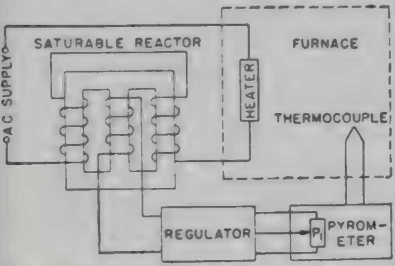

FIG. 25. Block diagram of electric furnace temperature regulator.

A thermocouple is located in the furnace, and the temperature is measured by a pyrometer having a motor-driven potentiometer P_1. The potentiometer arm, which is in the center when the temperature is correct, moves toward one end when the temperature is high and toward the other end when the temperature is low. The potentiometer controls the firing of thyratrons in the regulator, which supply direct current for the d-c winding of the saturable reactor.

ELECTRONIC VOLTAGE REGULATORS are often used for accurate regulation of generator voltage. Figure 26 illustrates the main elements of a voltage regulator for a d-c generator. A portion of the generator voltage appears across potentiometer P_1 and is balanced against a reference voltage provided by a battery. The difference between the two voltages is the error voltage which is amplified and applied across resistor R_1. The thyratron grid circuit includes the voltage across R_1 and an a-c voltage that lags the anode voltage by 90 degrees. Firing of the thyratron is controlled by the magnitude of the voltage across R_1. The thyratron supplies direct current to the generator field. If the generator voltage becomes too high, the voltage across R_1 increases, thus decreasing the portion of the cycle that the thyratron conducts. This decrease results in lower generator field current and, therefore, lower generator voltage. If the generator voltage becomes too low, the opposite sequence of events occurs and the regulator tends to increase the generator voltage to the desired value. The output voltage of the generator can be adjusted by means of potentiometer P_1. For simplicity the antihunting circuit is omitted in Fig. 26, and a single-phase half-wave thyratron rectifier is shown supplying the generator field.

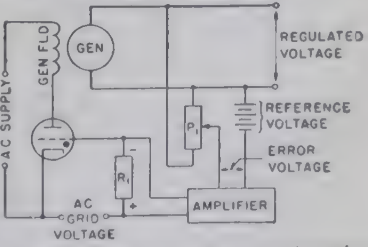

FIG. 26. Electronic voltage regulator for a d-c generator.

One commercial regulator of this type uses three thyratrons in a three-phase half-wave zigzag circuit to supply the generator field. In many cases the output of the rectifier is not great enough to supply the field of the main generator. An exciter is then used to supply the generator field, and the regulator supplies the exciter field. An a-c generator can also be used with this type of regulator by employing a voltage-indicating unit which rectifies the alternating voltage, smoothes it, and supplies a direct voltage input to the regulator.

SPEED REGULATION can be accomplished in a similar manner, as shown in Fig. 27. A d-c generator and motor are connected as an adjustable voltage or Ward Leonard drive in which the speed of the d-c motor is controlled by the voltage output of the generator. A d-c tachometer generator is coupled to the d-c motor. The fields of the motor and tachometer generator are supplied from a constant-voltage source. The speed of the d-c motor is then roughly proportional to the generator voltage, and the tachometer generator voltage is proportional to the speed of the motor. The output of the tachometer is fed into the regulator which supplies the field of the d-c generator. The regulator adjusts the generator voltage so that the speed of the motor is such that the tachometer voltage is held constant. Constant tachometer voltage results in constant speed of the d-c motor. The voltage regulator in Fig. 26 and the speed regulator in Fig. 27 are similar in that they both regulate for constant voltage output of a generator. However, the speed regulator presents a more difficult stability problem because of the added time delay introduced by the mechanical inertia of the d-c motor and load.

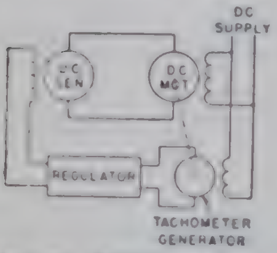

Fig. 27. Electronic speed regulator.

POSITION REGULATION is illustrated in Fig. 28. The d-c motor is required to follow the motion of the shaft represented by the handcrank. The output synchro is connected to the d-c motor and gives an indication of its position which, when compared with the input synchro, results in an error voltage that is proportional to the error for small errors. The error voltage is fed into the amplifier, which has a push-pull type output stage that supplies two bucking fields on the d-c generator. For zero error, the currents in the two fields are equal, the generator voltage is zero, and the motor does not run. If there is an error, the current through one of the fields will be greater than the other, resulting in a net excitation on the generator which produces a voltage, making the motor run in a direction to reduce the error.

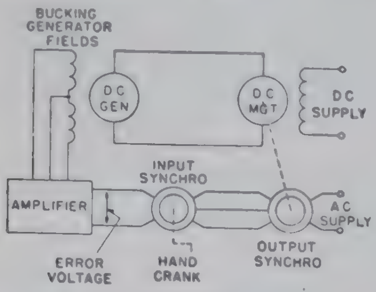

Fig. 28. Position regulator.

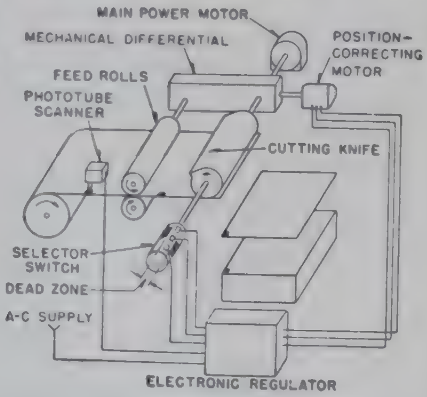

Fig. 29. Register regulator for positioning a printed sheet with respect to a cutting knife.

A PHOTOELECTRIC REGISTER REGULATOR for positioning a sheet relative to a reference mark is shown in Fig. 29. The roll of paper has been printed with a design and must be cut into separate sheets at the proper place with respect to the printing. The rotating cutter knife is driven by the main motor. The feed rolls are driven by the main motor and the position-correcting motor through a mechanical differential. Rotation of the position-correcting motor in one direction advances the reference mark, and rotation in the other direction retards the reference mark with respect to the cutter knife.

The photoelectric scanner consists of a light source, projecting and receiving lenses, phototube, and amplifier. Light is projected onto the sheet and is reflected back to the phototube. The phototube circuit is arranged to work on rate of change of illumination. When a reference mark passes under the light beam, the phototube current changes suddenly and a pulse is generated in the amplifier output. The output of the amplifier passes through the rotating selector switch and is introduced in the grid circuits of two thyratrons which control a set of reversing contactors. They, in turn, control the position-correcting motor. The selector switch is driven by the cutting knife shaft and has a dead zone in which the phototube amplifier output is connected to neither of the thyratron grid circuits. Rotation of the selector switch to one side of the dead zone connects the phototube amplifier output into the grid circuit of one thyratron, and rotation to the other side of the dead zone introduces the output to the grid circuit of the other thyratron. The regulating system is set up so that the phototube pulse occurs with the selector switch in the dead-zone position when the printed design is in the desired position with respect to the cutting knife. Under these conditions, neither thyratron conducts, and the position-correcting motor does not rotate.

Assume that the paper slips behind so that it is cut too soon. The phototube pulse will be connected by the selector switch to the grid of the thyratron controlling the contactor that connects the position-correcting motor to run in a direction that speeds up the feed rolls. The position-correcting motor will continue to run until the phototube pulse again occurs in the dead zone and the paper is in register. If the printed design gets ahead of the cutting knife, the selector switch sets up an opposite sequence of events which slows down the feed rolls, thus bringing the web into register.

The simple register regulator described above will regulate the position on the printed material within $\pm^1/_{32}$ in. More elaborate regulators such as multicolor press register regulators maintain an accuracy of 0.003 in. so that successive printing of the basic colors in multicolor printing can be accomplished without blurring.

BRAKES

Revised by R. M. Nardone

FRICTION BRAKES are used (1) to slow or stop a machine by converting its energy of motion into heat and (2) to control the speed of a descending load. Brakes may be classified as block brakes, band brakes, axial brakes, and load brakes.

The following points must be considered in the design of brakes: (1) Each part must have sufficient mechanical strength to withstand safely the maximum load that will come upon it during operation. (2) The pressure per unit area of surface must not be taken so high that excessive wear will result. (3) The coefficient of friction should be carefully considered; its value depends on the materials in contact, on the presence or absence of lubricating matter, and on the rate of slippage. With metal on metal, with increased velocity of slip, the coefficient of friction decreases from its value as the coefficient of friction of rest; the reverse, however, is true of leather. (4) The heat generated by the friction of the rubbing surfaces must be dissipated so as not to injure the brake.

16. BLOCK BRAKES

RESISTANCE OF BLOCK BRAKES. The simplest form of brake is the block brake, commonly used for railway car wheels, and in some forms for hoisting engines. In the car-wheel brake the resistance is not only that of sliding friction but also the resistance of cutting or grinding away the surface of the metals in contact. If P = total pressure acting normal to the sliding surface, pounds, μ = coefficient of friction, V = velocity of sliding, feet per minute, then the energy absorbed by the brake is $PV\mu$ ft-lb per min. Values of μ may be taken from Table 4, pp. 7-28 and 7-29. It should be noted that the value of μ is different for lubricated and unlubricated surfaces. If pressure P is great enough to squeeze out the lubricant, the value of μ increases, and the surfaces will cut and wear with an increase of temperature.

Block Brake Formulas. Various arrangements of block brakes are possible. Equations for different arrangements of single-block brakes are given in Table 1. If the faces of the sliding surfaces are grooved, the values given by eqs. 1 to 6 should be corrected as shown in the table. In the single-block brake, the reaction R of the brake shoe is opposed by an equal and opposite reaction R' at the bearing. The braking effect resulting from the friction of the journal can be neglected in designing the brake but should be considered in the design of the bearing. The single-block brake tends to bend the shaft. In the double-block brake (Fig. 1) reactions R of the two blocks are equal and opposite, and tendency to bend the shaft is eliminated. The braking force is equal to twice the value given by eq. 1. If the line of action of F passes either inside or outside of fulcrums O, the braking load is not the same at the two blocks, and a tendency to bend the shaft exists. The total braking load is the sum of the loads given by eqs. 3 or 5 as the case may be.

Table 1. Block Brake Formulas

P = force at end of brake lever, pounds; F = tangential force at rim of brake wheel, pounds; R = reaction between brake wheel and block, pounds; μ = coefficient of friction; $P(a+b) = Rb$.

	**Line of action of F passing through fulcrum O** For rotation in either direction $F = \mu R = \dfrac{\mu P(a+b)}{b}$ (1) $P = \dfrac{Fb}{(a+b)}\dfrac{1}{\mu}$ (2)
	**Line of action of F passing above fulcrum O** $F = \mu R = \dfrac{P(a+b)}{b\left(\dfrac{1}{\mu} \mp \dfrac{c}{b}\right)}$ (3) $P = \dfrac{Fb}{(a+b)}\left(\dfrac{1}{\mu} \mp \dfrac{c}{b}\right)$ (4) The minus sign is used for clockwise, and the plus sign for counterclockwise rotation.
	**Line of action of F passing below fulcrum O** $F = \mu R = \dfrac{P(a+b)}{b\left(\dfrac{1}{\mu} \pm \dfrac{c}{b}\right)}$ (5) $P = \dfrac{Fb}{(a+b)}\left(\dfrac{1}{\mu} \pm \dfrac{c}{b}\right)$ (6) The plus sign is used for clockwise, and the minus sign for counterclockwise rotation.
	For grooved brake wheel and block, Substitute $\dfrac{\mu}{\sin\alpha + \mu\cos\alpha}$ for μ in the above equations α = 1/2 included angle of groove faces.

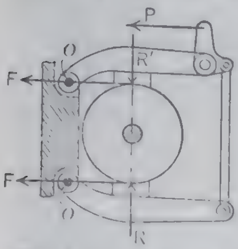

FIG. 1. Double-block brake.

17. BAND BRAKES

In wrapping band brakes, the torque exerted on the drum by friction is equal to the algebraic sum of the moments of the external loads applied to the band. The resultant load, represented by the difference between the tension on the tight side and the tension on the slack side, multiplied by the radius of the band, gives the torque or braking capacity.

Referring to Figs. 2 and 3,

$$F = T_1 - T_2$$
$$T_1 = T_2e^{\mu\alpha}$$
$$Q = FR = (T_1 - T_2)R = T_2R(e^{\mu\alpha} - 1) = T_1R\left(\frac{e^{\mu\alpha} - 1}{e^{\mu\alpha}}\right)$$

where F = total friction of the band on the brake wheel; T_1 = tension or pull on tight side of band, pounds; T_2 = tension or pull on slack side of band, pounds; R = radius of band,

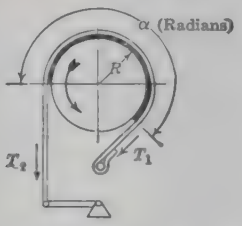

FIG. 2. Band brake, actuated on slack side.

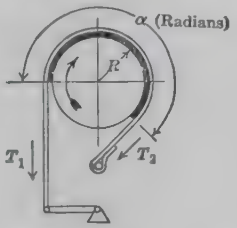

FIG. 3. Band brake, actuated on tight side.

feet; Q = torque developed by brake, pound-feet; e = 2.718; μ = coefficient of friction for lining material on drum; α = arc of contact in radians of band between points where T_1 and T_2 are taken.

Values of $e^{\mu\alpha}$ are given in Table 2. Table 3 shows various arrangements of band brakes and the formulas applicable thereto.

In general, for satisfactory results, the width of the band should be made approximately one-seventh the brake drum diameter. This diameter should range from $\sqrt[3]{2.4Q}$ to $\sqrt[3]{3Q}$ inches.

HEATING OF BAND BRAKES. The heat generated in a brake is a function of the braking torque and the number of revolutions of slip. The energy absorbed is

$$E = 2\pi Qn \text{ ft-lb}$$

Table 3. Formulas for Band Brakes

P = force at end of brake lever, pounds; T_1 = tension in tight side of band, pounds; T_2 = tension in slack side of band, pounds; $F = T_1 - T_2$ = tangential force at rim of brake wheel, pounds; μ = coefficient of friction between band and wheel; ϵ = base of Naperian system of logarithms = 2.71828; α = angle of contact of band with wheel, radians (1 radian = 57.296 degrees).

	$T_1 = F\dfrac{\epsilon^{\mu\alpha}}{e^{\mu\alpha}-1}$; $T_2 = F\dfrac{1}{e^{\mu\alpha}-1}$ For clockwise rotation, $P = \dfrac{Fb}{a}\dfrac{e^{\mu\alpha}}{e^{\mu\alpha}-1}$ For counterclockwise rotation, $P = \dfrac{Fb}{a}\dfrac{1}{e^{\mu\alpha}-1}$	(7) (8) (9)
	For clockwise rotation, $P = \dfrac{Fb}{a}\dfrac{1}{e^{\mu\alpha}-1}$ For counterclockwise rotation, $P = \dfrac{Fb}{a}\dfrac{e^{\mu\alpha}}{e^{\mu\alpha}-1}$	(10) (11)
	For clockwise rotation, $P = \dfrac{F}{a}\dfrac{b_2e^{\mu\alpha}-b_1}{e^{\mu\alpha}-1}$ For counterclockwise rotation, $P = \dfrac{F}{a}\dfrac{b_2-b_1e^{\mu\alpha}}{e^{\mu\alpha}-1}$ Unless $b_2 > b_1e^{\mu\alpha}$ the band will automatically grip the wheel and cause rupture of the band or some other part.	(12) (13)
	For clockwise rotation, $P = \dfrac{F}{a}\dfrac{b_2e^{\mu\alpha}+b_1}{e^{\mu\alpha}-1}$ For counterclockwise rotation, $P = \dfrac{F}{a}\dfrac{b_1e^{\mu\alpha}+b_2}{e^{\mu\alpha}-1}$ If $b_1 = b_2 = b$, for both cases, $P = \dfrac{Fb}{a}\dfrac{e^{\mu\alpha}+1}{e^{\mu\alpha}-1}$	(14) (15) (16)

If a weight is lowered through a given distance, by slipping of the brake, the energy absorbed by the brake is

$$E = Lh \text{ ft-lb}$$

The heat equivalent of energy is

$$H = \frac{E}{778.3}\text{ Btu}$$

and the temperature rise is

$$t_i = \frac{H}{WC} \tag{17}$$

where L = load, pounds; h = distance load is lowered, feet; n = revolutions of brake slip; t_i = increase in rim temperature, degrees Fahrenheit; W = weight of rim, pounds; c = specific heat of metal in drum; (c = 0.13 for cast iron and 0.116 for steel).

For best grades of asbestos friction lining, the permissible maximum temperature is 500 F. The temperature rise t_i will, therefore, depend on the initial or average low temperature of the drum.

For repeatedly applied brakes, the rate of heat dissipation must be equal to or greater than the rate of heat generation. The rate of dissipation per square inch of radiating area, denoted by $(t_1 - t_a)Xa$, varies between 0.15 and 0.36 Btu per min for t_i between 200 F and 400 F, respectively. Expressed in symbols,

$$H_d \geqq H_g$$
$$H_d = (t_1 - t_a)XaA_r$$
$$H_g = 42.4qMA_b$$

Therefore

$$(t_1 - t_a)XaA_r \geqq 42.4qMA_b$$

and

$$A_r \geqq \frac{42.4qMA_b}{(t_1 - t_a)Xa} \tag{18}$$

where t_a = temperature of surrounding air, °F; t_1 = maximum rim temperature, °F; X = cooling coefficient; a = temperature factor; M = horsepower capacity per square inch of brake; q = load factor, or portion of time that brake is in continuous use; A_b = total brake area, square inches; A_r = total radiating area, square inches; H_g = Btu generated per minute in brake; H_d = Btu dissipated per minute by the brake. Values for M depend on the service. A safe figure is 0.25.

18. CONE AND DISK BRAKES

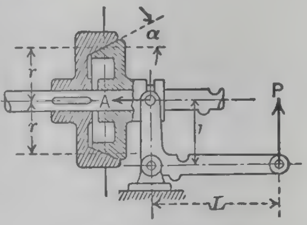

FIG. 4. Cone brake.

CONE BRAKES. Figure 4 illustrates one form of cone brake. Force P applied to the brake lever L causes axial movement of the brake cone into its mating shoe, thus creating resistance to the rotation of the member to which the shoe is attached. Let M = twisting moment on brake shaft, inch-pounds; r = mean radius of brake wheel, inches; P = pull on lever, pounds; $F = M/r$ = force at the circumference of the brake wheel, pounds; α = half angle of the cones; μ = coefficient of friction between brake wheel and shoe; A = axial pressure, pounds, along the cone shaft forcing the cones together; N = normal pressure on the cone, in order that the braking action shall overcome the turning moment; L = length of lever, inches; l = distance from fulcrum of brake lever to axis of cone. Then

$$F \gtrless 2\mu N \tag{19}$$

$$A = \frac{PL}{l} \tag{20}$$

$$N = \frac{A}{2(\sin\alpha + \mu\cos\alpha)} \quad (21) \quad \text{or} \quad \frac{A}{2\sin\alpha} \tag{22}$$

$$F \gtrless \frac{\mu A}{\sin\alpha + \mu\cos\alpha} \quad (23) \quad \text{or} \quad \frac{\mu A}{\sin\alpha} \tag{24}$$

$$P \gtreqless \frac{Fl(\sin\alpha + \mu\cos\alpha)}{\mu L} \quad (25) \quad \text{or} \quad \frac{Fl\sin\alpha}{\mu L} \tag{26}$$

Angle α usually ranges from 10 to 18 degrees. For cast iron on cast iron, μ can be taken as 0.12; for one surface of wood and the other of cast iron, $\mu = 0.25$ may be used.

From an experimental investigation of a cone brake by Professor H. Bonte (*Z. Ver. deut. Ing.*, Dec. 15, 1915), Professor Leutwiler (*Elements of Machine Design*, McGraw-Hill Book Co., p. 419) derives the following conclusions concerning eqs. 23 and 24: (1) When α is 15 degrees, the error introduced by using eq. 23 is large, while the agreement between the experimental results and those obtained by using eq. 24 is very close. (2) When α is 30 degrees, the experimental results lie between those obtained by eqs. 23 and 24. (3) When plotted, the curve representing the results obtained by eq. 24 lies above, but much closer to the experimental curve than that obtained by eq. 23. (4) For the angles 45 degrees and 60 degrees, the experimental points lie above those obtained by eq. 24, which in turn lie above the points obtained by eq. 23. (5) Apparently, the coefficient of friction is not constant, as generally assumed, but varies slightly with the pressure. As a result of this experimental investigation, Professor Bonte recommends that eq. 23, which apparently is incorrect, should not be used in the design of cone brakes or clutches.

DISK BRAKES. Like the cone brake, the disk brake depends on relative axial movement between fixed and moving elements. Where high torque is applied over a limited period of time, as in airplane landing wheel brakes, multiple-disk brakes serve well. Design principles are similar to those governing disk clutches (see Section 15, Article 9). In brakes the cooling problems will, in general, be more acute than in clutches.

19. INTERNAL BRAKES

Internal shoe brakes are used principally for automotive vehicles. The inertia of the vehicle is utilized to obtain the braking torque with a minimum of operating effort.

SINGLE-SHOE BRAKE. Referring to Fig. 5, let T = braking torque, pound-inches; f = coefficient of friction; r = radius of drum, inches; P = cam force on brake shoe, pounds; F = sum of all frictional forces on drum, pounds; ΣN = sum of all normal forces on drum, pounds; $\Sigma N'$ = sum of all normal forces on drum if there were no friction, pounds; and S = actuation factor represented by $\Sigma N/\Sigma N'$:

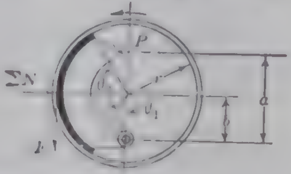

FIG. 5. Single-shoe internal brake.

$$A = \int_{\theta_1}^{\theta_2} \cos\theta \sin\theta \, d\theta = -{}^1/_4 (\cos 2\theta_2 - \cos 2\theta_1)$$

$$B = \int_{\theta_1}^{\theta_2} \sin^2\theta \, d\theta = -{}^1/_4 \ (\sin 2\theta_2 - \sin 2\theta_1) + \frac{\theta_2}{2} - \frac{\theta_1}{2}$$

$$C = \int_{\theta_1}^{\theta_2} \sin\theta \, d\theta = -(\cos\theta_2 - \cos\theta_1)$$

a, b θ_1 and θ_2 as shown in Fig. 5. Then

$$\Sigma N = P \times \frac{aC}{bB - f(bA + rC)} \text{ pounds}$$

$$\Sigma N' = P \times \frac{aC}{bB} \text{ pounds}$$

$$S = \frac{\Sigma N}{\Sigma N'} = \frac{bB}{bB - f(bA + rC)}$$

$$F = f\Sigma N \text{ pounds}$$

$$T = Fr, \text{ pound-inches}$$

EXAMPLE 1. Find ΣN, F, and T for the brake shown in Fig. 5 when $a = 10$, $\theta_1 = 25$ degrees, $b = 5$, $\theta_2 = 159$ degrees, $r = 8$, and $f = 0.3$.

Substituting in the foregoing formulas,

$$C = -(\cos 159° - \cos 25°) = 1.84$$

$$B = -{}^1/_4 (\sin 318° - \sin 50°) + \frac{159\pi}{360} - \frac{25\pi}{360} = 1.529$$

$$A = -{}^1/_4 (\cos 318° - \cos 50°) = -0.0251$$

Then

$$\Sigma N = P \times \frac{10 \times 1.84}{5 \times 1.529 - 0.3(5 \times -0.0251 + 8 \times 1.840)} = 5.64P \text{ lb}$$

and

$$\Sigma N' = P \times \frac{18.4}{7.645} = 2.405P \text{ lb}$$

$$S = \frac{\Sigma N}{\Sigma N'} = 2.34$$

$$F = 5.64 \times 0.3P = 1.692P \text{ lb}$$

$$T = 1.692P \times 8 = 13.536P \text{ lb-in.}$$

If P = 500 lb, T = 6750 lb-in.

With a symmetrical shoe in which a perpendicular to a radius passing through the anchor pin center divides the shoe in half for equal arcs of contact, the formula ΣN is somewhat simplified. In that case, since $A = 0$,

$$\Sigma N = P \times \frac{aC}{bB - frC}$$

The actuation factor S increases rapidly with an increase in coefficient of friction f. If too high a value of f is used, the brake is likely to grab.

TWO-SHOE BRAKE. Both shoes are shown pivoted at the same point in Fig. 6.

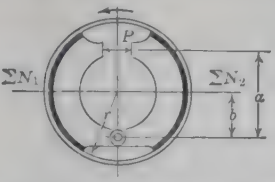

FIG. 6. Double-shoe internal brake.

For the drum rotation shown, the left-hand brake shoe is self-actuated while the right-hand shoe is not.

$$\Sigma N_1 = P \times \frac{aC}{bB - f(bA + rC)} \text{ lb}$$

$$\Sigma N_2 = P \times \frac{aC}{bB + f(bA + rC)} \text{ lb}$$

The sum of all normal forces is $\Sigma N = \Sigma N_1 + \Sigma N_2$. Also,

$$\Sigma N_1' = \Sigma N_2' = P\frac{aC}{bB}$$

For the left shoe,

$$S_1 = \frac{\Sigma N_1}{\Sigma N_1'}$$
$$F_1 = f\Sigma N_1$$
$$T_1 = F_1 r$$

For the right shoe,

$$S_2 = \frac{\Sigma N_2}{\Sigma N_1}$$
$$F_2 = f\Sigma N_2$$
$$T_2 = F_2 r$$

Total torque

$$T = T_1 + T_2$$

Example 2. Shoes symmetrical (Fig. 6): $\theta_1 = 30$ degrees, $\theta_2 = 150$ degrees, $a = 10$, $b = 5$, $r = 8$, $f = 0.3$.

For a symmetrical shoe:

$$\Sigma N_1 = P \times \frac{aC}{bB - frC}$$
$$C = -(\cos 150^\circ - \cos 30^\circ) = 1.732$$
$$B = -1/4(\sin 300^\circ - \sin 60^\circ) + \frac{150\pi}{360} - \frac{30\pi}{360} = 1.4802$$

Therefore,

$$\Sigma N_1 = 5.33P$$
$$\Sigma N_2 = 1.5P$$
$$\Sigma N_1' = 2.34P$$
$$S_1 = 2.28$$
$$F_1 = 1.599P$$
$$T_1 = 12.792P$$
$$S_2 = 0.281$$
$$F_2 = 0.45P$$
$$T_2 = 3.60P$$
$$T = 16.392P$$

From the foregoing, it will be seen that the braking torque of the assisted or self-actuated shoe is several times greater than the braking torque of the opposed shoe. Therefore, the assisted shoe will wear faster than the opposed shoe. If the cam which applies the actuating force on the shoes is fixed, P_1 on the assisted shoe will be less than P_2 on the opposed shoe and ΣN_1 will equal ΣN_2. In this case both shoes will wear equally.

PRESSURE SEALS

By L. S. Linderoth, Jr.

Loss of fluid and loss of pressure in hydraulic and pneumatic devices are prevented by the proper design and use of seals, packings, and gaskets.

CLASSIFICATION. Seals fall into two major classes: static and dynamic. Static seals or gaskets are used to prevent the flow of fluid across a static joint between two parts of a pressure vessel. A typical example is the gasket between the cylinder head and cylinder block of an automobile engine. Dynamic seals are used to prevent the flow of fluid across a sliding or rotating joint between two members of a hydraulic or pneumatic device. Typical examples are the piston packing in a cylinder and the shaft packing of a rotary pump.

A further classification divides seals into metallic and nonmetallic seals. Metallic packings or seals are illustrated by sheet lead gaskets and soft copper or aluminum washers. Nonmetallic packings are illustrated by sheet cork, sheet asbestos, leather, rubber, etc.

Subclassifications of nonmetallic seals are organic and inorganic seals, typical examples of which are leather, flax, and cotton for organic seals and asbestos and synthetic rubber for inorganic seals.

Seals may also be classified as to whether they are molded, sheet, or braided packings. Typical molded packings are cup packings, V rings, U cups, and O rings. Sheet packings are usually rolled from a mass of granulated or shredded packing material in a suitable binder.

The definitions of the words seals, packings, and gaskets are not exact. Generally speaking, any means to prevent the flow of fluid across a joint between adjacent members is referred to as a seal. If the seal is static it is frequently called a gasket. Means to prevent leakage in dynamic seals are most frequently referred to as packings. The synthetic metal-cased low-pressure shaft seals are referred to as "seals."

1. STATIC SEALS (GASKETS)

SIMPLE GASKET. Figure 1 illustrates the simplest type of gasket. It is cut by hand or blanked in a die from sheet stock to fit the particular joint it is to be used on. Gaskets are made from all kinds of material, such as paper, sheet cork, rubber, and asbestos. They must have some yield or compressibility in order to conform to the surface irregularities

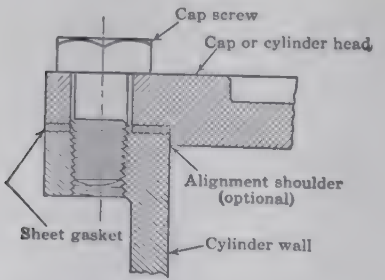

Fig. 1. Simple gasket or static seal. (Reproduced by permission from Selecting Hydraulic Seals, by L. S. Linderoth, Jr., *Machine Design*, Sept. 1944)

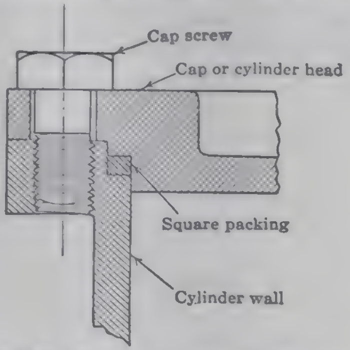

Fig. 2. Square packing. (From *Machine Design*, by permission)

If heat is present, as in an automobile engine or an air compressor, the gasket must be able to stand up under the highest temperature to be encountered. Bolts holding a cylinder head in place with a yielding gasket will have a load equal to gasket pressure plus cylinder pressure.

SQUARE PACKING. Figure 2 illustrates a form of gasket that gives a minimum load on the cylinder head bolts or manhole cover, as the case may be. A recess is designed into the joint between the two members, and a ring of cork is compressed in this space. Cork is the best material for this type of joint since it can be compressed to 75% of its original volume. Recommended dimensions are given in Table 1.

Table 1. Recommended Sections for Square Packing

Packing Ring Diameter, in.	Packing Thickness, in.
Up to 1	3/32
1 to 2	1/8
2 to 3	5/32
3 to 5	3/16
5 and over	1/4

The joints in Figs. 1 and 2 are used when disassembly is not a frequent occurrence. Assembly of a joint like Fig. 1 requires a new gasket for reliable results. Disassembly of a joint like Fig. 2 is difficult to accomplish without spoiling the gasket, particularly if the assembly is an old one.

Since the joint in Fig. 2 involves metal-to-metal contact the relation between the head and cylinder is accurate and can be predetermined. The joint in Fig. 1 depends on the bolt tension and the yield of the gasket material for the location of the head relative to the cylinder. This is not an accurate or a permanent relation.

O RING GASKET. Figure 3 illustrates the design of a seal for frequent disassembly. A standard O ring is used in an appropriate groove so laid out that assembly of the parts will not pinch the ring. Both surfaces against which the O ring seals must be as smooth as possible (mirror finish). The cylinder sleeve should have a slight bevel and rounded edge to prevent the O ring from being cut in assembly. Figure 4 is a variation of this design. The size of the O ring slot can be calculated from data in Fig. 5 and Table 2.

Note. C is computed to include clearance.

* V grooves are almost obsolete. See Air-Force-Navy Specification AN-P-74b for complete details

SOFT METAL GASKET. Figure 6 illustrates the use of a soft metal (copper or annealed aluminum) gasket. The two mating surfaces of the joint are serrated with sharp 60-degree vees directly opposite each other. These serrations sink into the soft metal gasket and effect a seal.

EXTRA-HIGH-PRESSURE SEALS. Figure 7 illustrates an extra-high-pressure seal. A wedge-shaped groove in the mating surfaces holds a soft metal ring. The bolts seat the ring into the grooves. Such a seal can be used for pressures up to 20,000 psi. Figure 8 illustrates a form of extreme pressure packing. As can be seen in the cross section, this type of packing is complex. It was developed by Dr. P. W. Bridgman at Harvard University for experiments at pressures on the order of a million psi.

Mention should be made of various plastic compounds that are used to make gaskets. They are marketed in collapsible lead tubes for ease of handling. The paste or plastic is extruded from the tube and spread over the surface of the joint with a spatula or other suitable tool. Materials are available that will stand high temperatures, will act as a cement, and will remain plastic, depending on the particular requirements. These pastes can be had both waterproof and/or oilproof.

2. DYNAMIC SEALS (PACKINGS)

SIMPLE PACKINGS. Figure 9 illustrates the simplest type of dynamic seal. It may be either reciprocating or rotating. The packing material can be cotton, flax, or other fiber, either twisted or braided. The proportions of the gland depend on the diameter of the rod, a $^1/_2$-in. rod having a gland of $^1/_4$-in. radial dimension and a 2-in. rod one of $^1/_2$-in. radial dimension.

An improvement over the internally threaded gland is shown in Fig. 10. Here the gland is smooth, and the packing material can flow more readily to form a tight seal with a minimum pressure from the gland nut.

VEE PACKINGS. Figure 11 illustrates a dynamic seal using a preformed or molded packing ring with a V-shaped cross section. This type of packing reduces the friction between packing and moving rod. By using three or more V rings the pressure drop against which each ring must operate is greatly diminished, resulting in longer life and lower friction. Likewise, by using multiple layers of V rings they can be cut and assembled over the rod without the need of a free end on the rod. The joints are staggered. Figure 12 is a spring-loaded self-adjusting design of V ring assembly. Details of size and design of V packings are shown in Fig. 13.

Fig. 13. Dimensions of Vee packing. (From *Mechanical Packings Manual*, by permission)

Cross-sectional width is $CS = (A - B)/2$, where A is the outside diameter of the stuffing box or packing recess or inside diameter of the cylinder and B is the outside diameter of the piston rod or inside diameter of the machined recess on the piston head (see Fig. 13). Ten cross-sectional widths have been agreed upon as standard by the Mechanical Leather Packings Manufacturers division of American Leather Belting Association: $^3/_{16}$, $^1/_4$, $^5/_{16}$, $^3/_8$, $^7/_{16}$, $^1/_2$, $^5/_8$, $^3/_4$, $^7/_8$, and 1 in. For new designs the six sizes $^1/_4$ to $^5/_8$ in. should be adhered to as they are the sizes generally used.

Thickness. Correct thickness T (Fig. 13) is $T = CS/4$, the absolute maximum being $CS/3$. For almost any job $^1/_8$-in. thickness is sufficiently large, though $^5/_{32}$- or $^3/_{16}$-in. can be used if cross section CS allows.

Dimensions. Formulas for the dimensions in Fig. 13 are:

S = stack height of one packing = $1.414T$
H = height of one packing = $CS/2 + T - {}^1/_{64}$ in.
R = outside radius of packing = radius in female adapter = $T + {}^1/_{64}$ in.
G = radius for male adapter = $CS/2 = (A - B)/4$
X = sealing clearance = $0.207CS$
Y = flexing allowance = $0.15CS$
E = female adapter groove depth = $0.7G - 0.22R$
F = optional (preferably equal to T)
K = optional ($CS/2$ is desirable)

Dimensions C and D, the inside and outside diameters of the female adapter, should have as close a fit as possible to the mating parts.

When the female adapter is made as shown in Fig. 13 the space created by the differential in angles of the Vee and adapter allows the legs to flex toward the surfaces to be sealed.

On initial installation it is sometimes necessary to tighten the follower onto the set to get a slight initial spreading of Vees to seal properly.

The differential of angles between the Vees and female adapter and the shape of the male adapter shown on the left promote the spreading action, leave room for the legs to flex toward the surfaces to be sealed, and generally improve the performance of the installation.

When the Vee packings have served their normal service life, but a few hours more run is required; by tightening the follower and compressing the Vees, the set will respond to compression.*

FIG. 14. Design of molded synthetic V rings standardized by the Army and Navy.

Molded synthetic V rings have been standardized by the Army and Navy under AN6225. Design details of these rings and adapters are given in Fig. 14. The AN specification material from which these rings are molded is used for operating temperatures ranging from −65 to +160 F. Other compounds can, of course, be used to give operating characteristics suitable for higher temperatures. For complete data see the Army-Navy standard AN6225, or manufacturers' catalogs.

---

* From *Mechanical Packings Manual*, published by Graton and Knight Co., Worcester, Mass.

FLANGE PACKING. Figure 15 illustrates a flange packing. This molded or preformed packing is available in standard dimensions. It is frequently installed with a means for insuring pressure of the packing lip against the piston, rod, or shaft. The use of garter springs and flat leaf springs for this purpose is quite common.

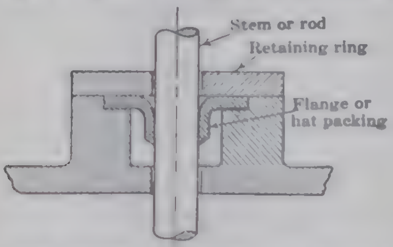

Fig. 15. Flange packing. (From *Machine Design*, by permission)

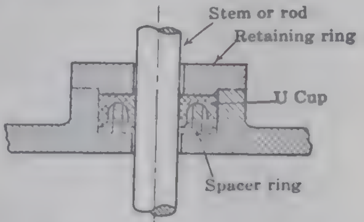

Fig. 16. Dynamic seal using molded U cup. (From *Machine Design*, by permission)

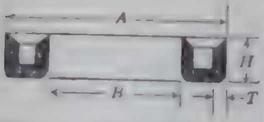

Fig. 17. Dimensions of U packing. See Table 3.

U PACKINGS. Figure 16 shows a shaft or piston rod seal using a molded U cup. It is fitted in a gland of suitable proportions and held in place by a permanently located cap or retaining ring. The U cup is supported by a spacing ring as illustrated. Leather U cups are molded in sizes shown in Fig. 17 and Table 3. The gland dimensions and spacer are made to suit these sizes.

Molded U cups are available in synthetic rubber for use in oil hydraulic systems. They conform to U. S. Army and Navy specifications, but can also be made in special sizes. See catalogs by manufacturers such as Graton and Knight, E. F. Houghton and Co., Linear Inc., and Victor Manufacturing and Gasket Co.

Table 3. Recommended Proportions for U Packings

See Fig. 17

(Reprinted by permission from *Mechanical Packings Manual*, Graton and Knight)

A Outside Diameter (Packing Carried in Gland or Recess), in.	*B* Inside Diameter, in.	*H* Height of Packing, in.	*T* Thickness of Leather, in.
1 3/4	1	3/8	1/16
3	2	7/16	3/32
4	3	1/2	1/8
5	4	5/8	1/8
6 1/4	5	5/8	5/32
7 1/4	6	3/4	5/32
8 1/2	7	3/4	3/16
9 1/2	8	7/8	3/16
10 1/2	9	7/8	3/16
11 1/2	10	1	3/16
13 1/2	12	1	3/16
15 1/2	14	1	3/16
17 1/2	16	1	3/16
19 1/2	18	1 1/4	3/16
21 1/2	20	1 1/4	3/16
23 1/2	22	1 1/4	3/16
25 1/2	24	1 1/4	3/16
29 3/4	28	1 1/4	3/16
33 3/4	32	1 1/4	3/16
37 3/4	36	1 1/4	3/16
42	40	1 1/2	3/16
46	44	1 1/2	3/16
50	48	1 1/2	3/16

The above table is sound practice, but greater heights can be furnished as required for existing equipment. It should be remembered that friction is directly proportional to the area of the U contacting the surface to be sealed and that unnecessary height increases friction but adds nothing to the performance or life of the packings. On new designs, adhere to values given in this table.

HIGH-PRESSURE PACKINGS. The packing in Fig. 18 seals relatively high pressure and occupies a minimum of space. It is the simple O ring, a patented device that is available in a large range of sizes that were standardized under Army and Navy specifications, AN-6227. It is usually molded from a synthetic rubber composition suitable for use at temperatures ranging from −65 to +160 F. Figure 5 and Table 2 give the dimensions of the groove for all standard sizes of the packing. The important point to watch in using O-ring packings is the production of extra smooth, 10 microinch or better, surfaces. These smooth surfaces can be produced inexpensively with modern honing and superfinishing methods. The assembly of units using O rings must be done with extra care to prevent the ring's being damaged by sharp corners. Rings should be wet with oil before assembly is attempted.

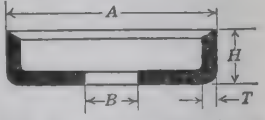

FIG. 22. Dimensions of cup packings. See Table 4.

Figures 19, 20, and 21 show, respectively, the assembly of V rings, U cups, and cup packings on double-acting pistons. The V ring assembly shows two sets of packings facing in opposite directions. The chevrons formed by the V section face away from each other so that no pressure can build up between the two sets. Means are provided to lock the adjustment since once the assembly is complete it is difficult to reach this adjusting nut.

Figure 20 is shown assembled in a fixed relation. Fluid pressure is depended on to exert pressure against the packing lip to effect a seal. This is possible with a U cup or cup packing whose lip is flexible but is not practical with a chevron-type packing. Figure 22 and Table 4 give dimensions of the cup packing illustrated in Fig. 21. Over 24		2	1/8	3/16

Table 4 gives the generally accepted proportions for cup packings as accepted by the Mechanical Leather Packings Division of the American Leather Belting Association.

The height *H* should never exceed values shown. Increased height does not improve seal, but increases friction on the cylinder wall.

The diameter of the hole or holes and their location are optional, but care must be exercised to leave ample area on the bottom of the cup to anchor the cup securely to the piston head or plunger.

cup packing molded from properly treated leather makes the best piston packing for water pumps and is widely used on pumps for domestic water supplies on farms and suburban homes. It is also frequently used on the pistons of small air pumps such as bicycle pumps and atomizing spray equipment. It must be properly supported by the piston and a retaining ring or washer.

Figure 23 shows the use of O rings in piston packings. This type of packing is shown in detail in Fig. 5. All dimensions conform to Army and Navy standards AN-6227. O rings when used alone are good for pressures up to 1500 psi. When used with back-up rings of leather they can be used up to 3000 psi. The problem at high pressures is to prevent extrusion of the ring into the piston-cylinder clearance. Various materials such as bakelite, leather, and soft metals have been tried for back-up rings. When hard materials are used the ring must be split or the piston assembled from parts having the groove in them. Rectangular groove dimensions for use with O rings and back-up washers are listed in Table 5.

Only one O ring is recommended in any one installation, it should be noted. Oil will be trapped between rings used in multiple, thereby increasing the packing friction and de-

Table 5. Proportions of Rectangular Grooves for O Rings and Back-up Washers

Dash No.	Section Diameter Nominal	Gland Width *C* max (Fig. 5)		Minimum Squeeze	Groove Length +.005 −.000	
		Dynamic	Static		One Back-up Ring	Two Back-up Ring
1–7	1/16	.057	.052	.010	.139	.206
8–14	3/32	.090	.083	.010	.171	.238
15–27	1/8	.123	.113	.012	.208	.275
28–52	3/16	.188	.173	.017	.311	.410
53–88	1/4	.240	.220	.027	.408	.538

Piston groove diameter equals bore diameter (at plus tolerance) minus $2C$. Rod gland groove diameter equals piston groove diameter (at minus tolerance) plus $2C$.

Groove length D = actual W of O ring + nominal thickness of leather or leathers + 1/2 (plus tolerance of all components).

creasing its life. The rectangular groove will give slightly lower starting friction and is easier to produce to the required dimensions. It is the preferred form, and the V-groove for O rings is becoming obsolete.

In the design of single-acting pistons a choice of packing designs is indicated in Figs. 24 and 25. Pistons may be "outside" packed as in Fig. 24, having the advantage of ease of maintenance and adjustment; or "inside" packed as in Fig. 25, having the advantage of a smaller overall cylinder size, but difficult maintenance features. The choice of which design to use will depend on the circumstances and factors affecting the particular situation under consideration: space, weight, leeway from a perfect seal, etc.

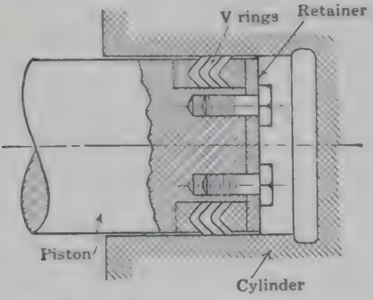

Fig. 25. Inside-packed single-acting piston. (From *Machine Design*, by permission)

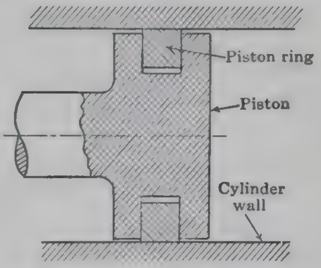

Fig. 26. Piston ring used as dynamic seal. (From *Machine Design*, by permission)

Figure 26 illustrates the use of a piston ring as a dynamic seal. Single or multiple rings may be used, depending on the pressure to be sealed. They are used primarily under high-temperature conditions where nonmetallic packings would quickly fail. It is also used because of its low packing friction.

Figure 27 shows a piston design that is used when minimum friction is required and some leakage can be tolerated. Small annular grooves are turned or ground in the cylindrical surface of the piston to insure equal distribution of pressure around the piston, thereby causing it to stay in the center of the cylinder. These grooves are made about $^1/_{16}$ in. wide by $^1/_{32}$ in. deep for a 1-in. piston, proportionately larger for larger piston diameters.

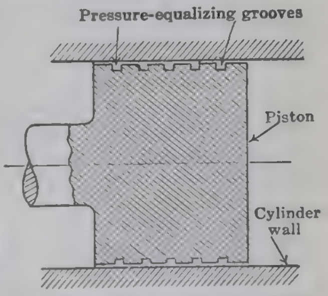

Fig. 27. Low-friction piston design where slight leakage is permissible. (From *Machine Design*, by permission)

The leakage past such a piston can be accurately calculated if the dimensions of the cylinder and piston are known accurately; and if the pressure drops across the piston, the total effective length of the piston and the absolute viscosity of the oil are known. The basic formula * used for flow between two parallel planes is

$$Q = \frac{1}{12} \frac{C^3 \times \Delta p \times W}{\mu \times l}$$

in which Q is flow, cubic feet per second; C is space between planes, feet; W is width of flow path, feet; Δp is pressure drop, pounds per square feet between points; l is distance in feet along the path of flow; and μ is the absolute viscosity in slugs/foot-second. For a piston in a cylinder l is the length of the piston, C the radial clearance, and W the circumference $(2\pi R)$. The formula would then become

$$Q = \frac{1}{12} \frac{C^3 \times \Delta p \times 2\pi R}{\mu \times l} = \frac{\pi}{6} \times \frac{C^3 \times \Delta p \times R}{\mu \times l}$$

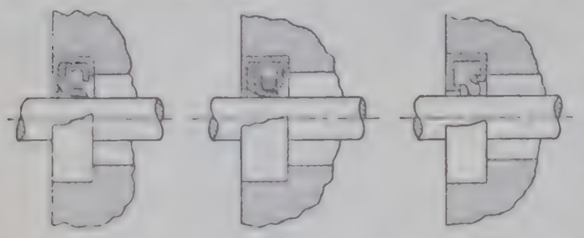
Q is then multiplied by a factor 2.5 to give the flow for maximum eccentricity between piston and cylinder bore. Any consistent units of measurement can be used in place of those indicated.

SHAFT SEALS have gained considerable popularity for use in connection with ball-bearing installations. They are of three basic designs, as shown in Fig. 28, namely, leaf spring (*a*), garter spring (*b*), and self-sealing (*c*). There is little choice between reliable makes of shaft seals.

---

* C. E. Grosser, Hydraulic leakage can be controlled, *Machine Design*, Aug. 1942.

The sealing lip is compounded to suit the average operating conditions. The primary criterion is surface speed under the sealing lip. It is important that the seal is designed for the shaft or surface speed at which it will be used. If a slow-speed design is used for high shaft speeds, excessive friction will develop and result in overheating and early destruction of the seal. The manufacturer's ratings and recommendations should be carefully followed.



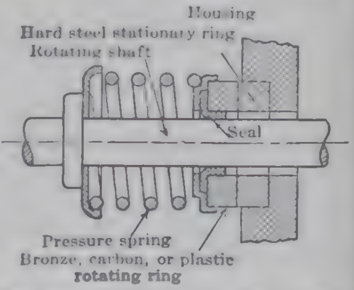
(*a*) (*b*) (*c*)

FIG. 28. Seals for antifriction bearings. (From *Machine Design*, by permission)

For shaft installations requiring a relatively permanent seal and minimum maintenance to preserve perfect sealing, the steel-to-graphite lapped seal is the proper choice. Such a seal is illustrated in Fig. 29. Many variations of this design are available, some using bellows and some rubber as the means of sealing the graphite or bronze ring to the shaft. The main operating feature is the use of lapped surfaces of mutually low coefficient friction materials for the sliding surfaces.

FACTORS TO BE CONSIDERED IN PACKING DESIGN. Surface Finish. Too much cannot be said regarding the importance of having smooth surfaces for packings to operate against. In order that dynamic seals may have a maximum life every effort must be made to have and to maintain smooth surfaces over which the packing slides. The ideal surface is one machined to a finish of 10 to 15 microinches rms. This can be done by fine grinding or honing. It is interesting to note that if the surface is smoother than 10 to 15 microinches, lubrication of the packing becomes difficult as the surface is too smooth to hold oil and unless the packing material is porous and holds its own lubricant trouble may result.

Choice of Packing Material. Choice of a packing material will depend on the type of installation and fluid being used, also on the temperature at which the packing will operate.



Housing
Hard steel stationary ring
Rotating shaft
Seal
Pressure spring
Bronze, carbon, or plastic rotating ring

FIG. 29. Lapped seal. (From *Machine Design*, by permission)

Leather, a universal packing material, is used for a wide variety of packings. It is usually molded and impregnated with waxes or oils best suited for a particular service condition. It has a very long life compared to rubber, but does not give as good an initial seal.

Synthetic rubber is not as porous as leather, and for this reason it has many applications where leather cannot be used. Rubber tends to cold bond to metal, and if dynamic rubber seals stand idle too long they may resist motion to the point of breaking machine parts. This tendency has been overcome in recent synthetic compounds. Reference is made to packing manufacturers' manuals which cover the choice of materials more completely.

Pneumatic devices in general are best designed with a porous packing, such as leather which can be self-lubricating for dynamic seals.

Where temperatures are high, asbestos compounds are needed. Recent developments in silicone rubber should yield good high-temperature packings. However, silicone rubber so far is good only for static seals because of its low tensile strength and poor wearing quality.

Valve stems are usually packed with some form of wick or braided packing impregnated with a suitable grease or graphite to act as a lubricant.

Rotating pump shafts are sometimes packed in a manner similar to valve stems. More recent designs employ molded V rings or rotating seals similar to those shown in Fig. 30. The rotating metallic and graphite seals, while more expensive in the initial installation, give less trouble and have lower maintenance costs.

Proper Support for the Packing or Seal. The finest packing material will fail if not properly used in a given installation. The backing rings and adapters for V rings, V cups, and other molded packings must be of proper dimensions to support the packing materials and allow proper distribution of the pressure load on the packing. Clearance between cylinder and piston and between rod and bearing must be at a minimum to avoid excessive packing extrusion. Groove dimensions for O rings must be held to proper tolerances. Packing manuals and manufacturers' specifications should be carefully followed.

Assembly of Packings. Great care should be taken during the assembly of packings into hydraulic or pneumatic units to insure that these packings are clean and free from defects. Extreme care must be exercised in passing packings over threads on a piston rod or across sharp valve ports in a cylinder to avoid cutting the packing. Shim steel ferrules used over the threads safeguard the packings. This advice applies equally to rubber or leather packings. On assembling mating surfaces with a gasket, the gasket should be free from tears or breaks and the metal surfaces must be clean. The thinnest possible gasket that will do the work should be used.

Care and Maintenance. Thought should be given in the design of dynamic seals to the amount of servicing they will require. This amount will be greatly influenced by operating conditions: temperature, cleanliness, ratio of operating to shut-down time, lubrication of packing, etc. If adjustments are necessary in a given packing design, they should be accessible and easy to make. The ability to replace worn packings without considerable disassembly of mechanisms is of great value.

New Data. Because of rapid advances in the art of packing design, the development of new materials, and the standardization of data throughout the hydraulic industry, it is recommended that engineers check with packings manufacturers to be sure of using the latest available information. Publications of the Joint Industry Conference (JIC) in particular should be consulted.

COTTERED JOINTS, PIN JOINTS, AND TAPERS

3. COTTERED JOINTS

A cotter is a form of key used to join parts subjected to a tension or compression, tending to separate them. The taper of cotters should not exceed $^1/_2$ in. per ft of length unless a locking device is used. Various forms of cotters are given in Figs. 1 to 7 and in Table 1, which shows the proportions of the joint. The function of the gib, in the gib and cotter joint (Figs. 2 and 3) is to prevent spreading of the strap. When a gib is used, the sides of the hole are made parallel, the taper being given to the gib. Where two cotters are used, as in Fig. 3, the taper is divided equally between them. The tapered joint (Fig. 6) usually is of permanent character. The cotter is removed only when the members which it holds are to be repaired or replaced. It is largely used for joining pistons and piston rods.

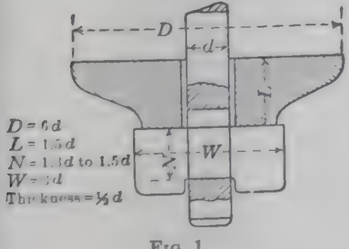

FIG. 1

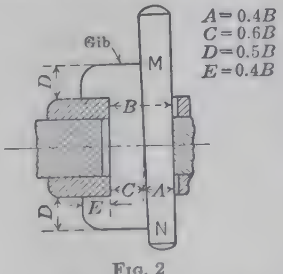

FIG. 2

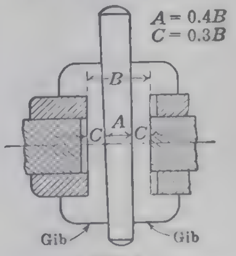

FIG. 3

One form of grip, taken from *Machine Design Construction*, by Spooner, is shown in Fig. 7. The joint may fail in any one of ten ways.

Table 1. Dimensions of Cottered Joints

(See Figs. 4–6)

	Rod	Cotter	Dimensions								
			A	*B*	*C*	*D*	*E*	*F*	*G*	*H*	*J*
Fig. 4	Wrought iron	Steel	0.3*d*	1.21*d*	1.75*d*	1.5*d*	2.4*d*	0.42*d*	0.8*d*	1.6*d*	0.8*d*
Fig. 5	Steel Wrought iron	Steel Wrought iron	0.3*d*	1.21*d*	—	1.5*d*	—	0.5*d*		1.6*d*	1.0*d*
Fig. 6	Steel	Steel	0.25*d*	—	—				0.9*d*	0.9*d*	0.9*d*

Notation. s_t = ultimate strength of rod ends in tension; s_s = ultimate strength of cotter in shear; s_b = ultimate strength of bearing surfaces = say, $2s_t$; s'_s = ultimate strength of steel or iron to resist shear in direction parallel with fibers; all in pounds per square inch; F = axial force causing rupture of the joint. The significance of the other quantities in the equations is shown in Fig. 7, all dimensions being taken in inches.

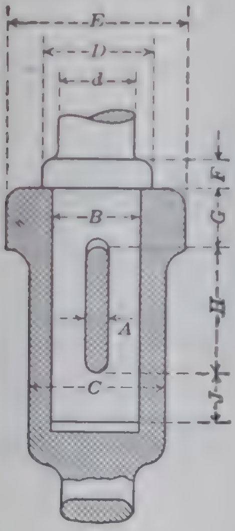

FIG. 4

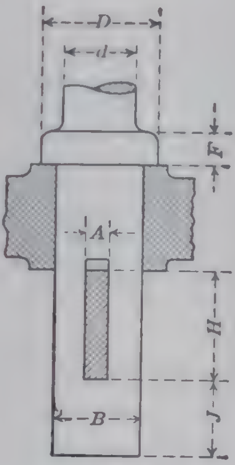

FIG. 5

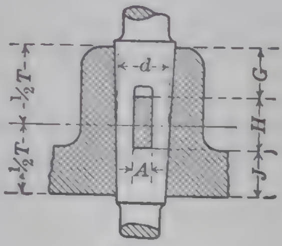

FIG. 6

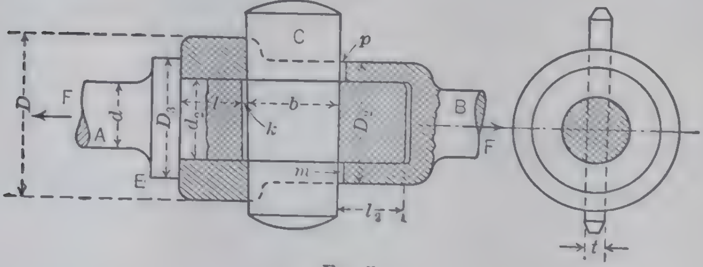

FIG. 7

1. The rods may fail in tension at *A* or *B*, in which case the external load

$$F = \tfrac{1}{4}\pi d^2 s_t$$

2. By the rod end tearing across the cotter hole; $F = (\tfrac{1}{4}\pi d_2^2 - d_2 t)s_t$. Equate cases 1 and 2 and let $t = \tfrac{1}{4}d_2$; then

$$d_2 = 1.21d, \quad d = 0.82d_2, \quad \text{and} \quad t = 0.3d$$

For joints with all parts either wrought iron or steel, the breadth of the cotter usually is about 1.6*d*.

3. By the socket tearing across the cotter hole; then

$$F = [{}^1/_4\,\pi(D_2^2 - d_2^2) - (D_2 - d_2)t]s_t$$

whence by equating case 1, $D_2 = 1.63d$, or allowing for clearance, say, $D_2 = 1.75d$.

4. By double shearing of the cotter,

$$F = 2bts_s \quad \text{and} \quad b = 1.31ds_t/s_s$$

or $1.06d_2s_t/s_s$, where b = mean breadth of the cotter.

5. By crushing the cotter bearing surface in the rod end; $F = d_2ts_b$.

6. By crushing the cotter bearing surface in socket; $F = t(D - d_2)s_b$ and $D = 2.42d$.

7. By shearing socket end; $F = 2\,[l(D - d_2)s'_s]$.

8. By shearing rod end; $F = 2l_2d_2s'_s$. $l = l_2 = 0.648d$; make l from $0.75d$ to $1.0d$.

9. By crushing the collar E; $F = {}^1/_4\,\pi(D_3^2 - d_2^2)s_b$ and $D_3 = 1.3915d$, say, $1.4d$.

10. By shearing the collar E off the rod end; $F = d_2\pi t_2s'_s$ and $t_2 = 0.413d$, say, $t_2 = 0.42d$, where t_2 is thickness of collar.

4. PIN JOINTS

STRENGTH OF KNUCKLE JOINT PIN. (Spooner, *Machine Design.*) The proportions of a forked pin joint or knuckle joint are shown in Fig. 8. If there is no bending action, the pin will fail in double shear. If d = diameter of rod, d_1 = diameter of the pin, s_t = tensile strength of rod, s_s = shearing strength of pin, pounds per square inch, = say, $0.8s_t$, then

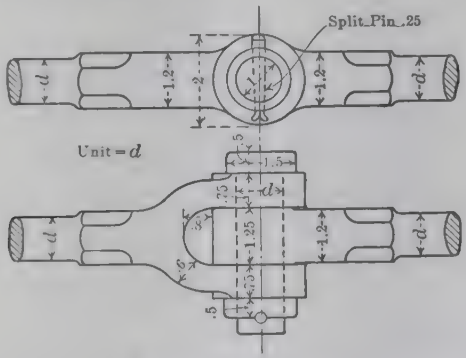

FIG. 8. Knuckle joint.

$$ {}^1/_4\,\pi d^2s_t = 2({}^1/_4\,\pi d_1^2s_s) \quad \text{or} \quad d_1 = 0.79d$$

Unwin shows that where bending occurs and the joint is subjected to stresses reversing in sign, a skin stress of 5400 psi, due to bending, will not be exceeded if the diameter of the pin $= 0.0224\sqrt{F}$, where F = axial force in the rod.

SAE STANDARD ROD ENDS AND PINS. Proportions of adjustable and plain yokes, and eyes and pins, are given in Fig. 9 and Table 2.

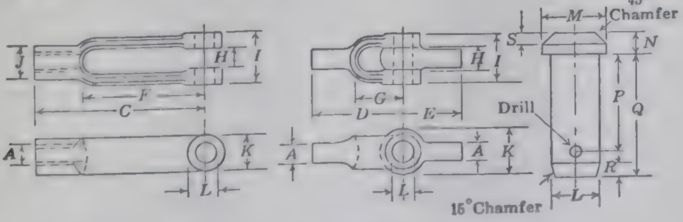

FIG. 9. SAE standard rod ends and pins. See Table 2.

5. TAPERS

AMERICAN STANDARD TAPER. The ASA standards for self-holding tapers comprise twenty-two sizes. The three smallest sizes (Table 3) are taken from the Brown and

* Corners at entrance side of keyways shall be chamfered at 45 deg as follows: No. 3, 3/64 in.; all other sizes 1/16 in. deep.

† These sizes are continued in the tang drive series for the present to meet special needs.

Tolerances are:

For diameter of shank at gage line (*A*): All sizes, +0.002 − 0.000.

For diameter of hole at gage line (*A*): All sizes, +0.000 − 0.002.

For thickness of tang (*E*): Up to and including No. 5, +0.000 − 0.006. Larger than No. 5, +0.000 − 0.008.

For width of knockout keyway (*N*): Up to and including No. 5, +0.006 − 0.000. Larger than No. 5, +0.008 − 0.000.

For concentricity of tang (*E*) with center line of taper: Up to and including No. 5, 0.0035 (indicator reading). Larger than No. 5, 0.005 (indicator reading).

For concentricity of knockout keyway (*N*) with center line of taper: Up to and including No. 5, 0.0035 (indicator reading). Larger than No. 5, 0.005 (indicator reading)

Tolerances on fractional dimensions, ±0.010 unless otherwise specified.

Sharpe series and have a nominal taper of $^1/_2$ in. per ft. The next eight sizes (Table 3) are taken from the Morse series and have a nominal taper of $^5/_8$ in. per ft. The eleven largest sizes (Table 4) are based on a taper of $^3/_4$ in. per ft.

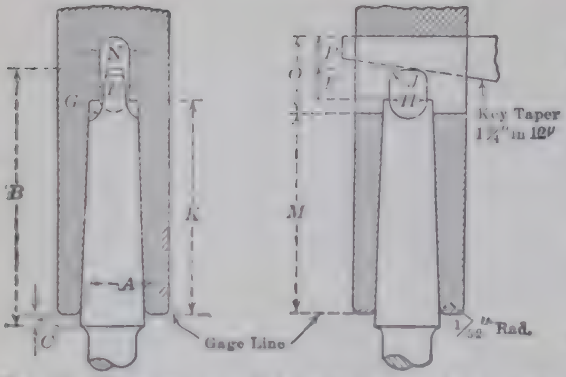

FIG. 10. Taper with tang drive, shank retained by friction. See Table 3.

The eleven smaller sizes (Table 3) employ a tang drive and may be retained entirely by friction (Fig. 10). Of these the six largest may be retained by a holdback key (Fig. 11). Removal of the shank from the socket is effected by starting with a drift key.

The eleven largest sizes (Table 4) employ a key drive. The shank may be retained in the socket either by a holdback key (Fig. 12) or a drawbolt (Fig. 13).

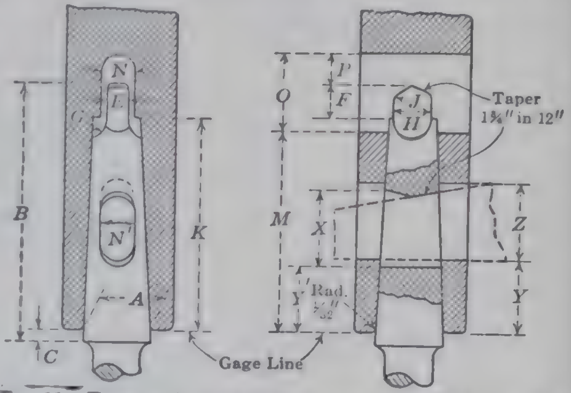

FIG. 11. Taper with tang drive, shank retained by key. See Table 3

Steep Taper. Tapers listed in Table 5 have an angle sufficiently large to permit self-release. Retention of the shank in the socket is dependent on a positive locking device. The taper fit serves only to maintain alignment.

OTHER TAPERS. Prior to the adoption of the American Standard tapers several tapers were in use for spindles and drill shanks. The more important are listed in the following paragraphs.

Reed Lathe Center Taper. This comprises a series of ten tapered lathe centers of standard dimensions. Size is based on the size of the lathe.

Standard Tool Co. Taper. Used for twist drill shanks, this series comprises seven tapers numbered from 1 to 7. Taper ranges from 0.6 to 0.625 in. per ft. Dimensions are approximately similar to those of the corresponding Morse tapers.

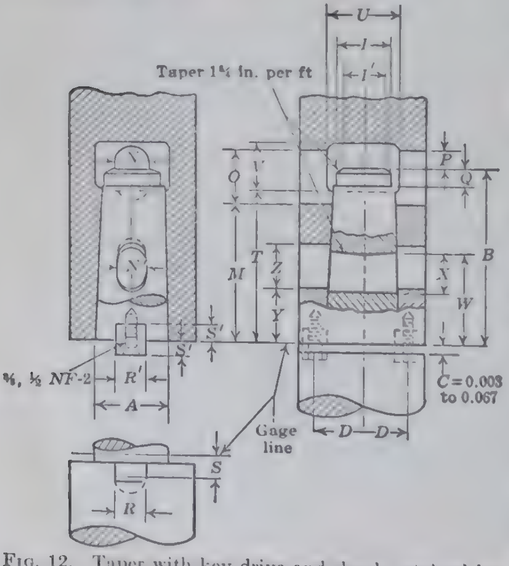

FIG. 12. Taper with key drive and shank retained by key. See Table 4.

Morse Tapers. Original series comprises eight tapers numbered from 0 to 7. The American Standard includes those from 1 to 7 with the addition of No. 4 $^1/_2$ (see Table 3).

Cleveland Twist Drill Tapers. This series comprises seven tapers numbered from 0 to 6, with taper ranging from 0.6 to 0.63 in. per ft. Dimensions are approximately the same as the corresponding Morse taper numbers.

Sellers Taper. This series consists of a set of seven sizes of standard shank-and-socket parts with a taper of $^3/_4$ in. per ft. Intermediate sizes can be fitted to each other, and keys are provided for driving and for knockout.

Brown and Sharpe Taper. Complete series consists of eighteen tapers numbered from 1 to 18. The American Standard includes the first three of these (see Table 3).

* Corners at entrance side of keyways shall be chamfered at 45 degrees as follows: No. 200 to 350, inclusive, 1/16 in. deep; No. 400 to 600, inclusive, 3/32 in. deep; No. 800 to 1200, inclusive, 1/8 in. deep.

† Taper is 0.75 in. per ft for all sizes in this table.

‡ Width is *N* = *N′*.

§ Width is equal to *N′*.

Tolerances are:

For diameter of shank at gage line (*A*): All sizes, +0.002 − 0.000.
For diameter of hole at gage line (*A*): All sizes, +0.000 − 0.002.
For width of drive keyway (*R′*): In socket, +0.000 − 0.001.
For width of drive keyway (*R*): In shank, +0.010 − 0.000.
For width of knockout keyway (*N*): +0.008 − 0.000.
For concentricity of drive keyway (*R*): With center line of spindle, 0.003.
For concentricity of drive keyway (*R′*): With center line of spindle, 0.001.
For concentricity of knockout keyway (*N*): With center line of spindle, 0.007.
Tolerances on fractional dimensions: ±0.010 unless otherwise specified.

Jarno Taper. This series comprises nineteen tapers numbered from 2 to 20, with a taper of 0.6 in. per ft. The number of a taper is its diameter in tenths of an inch at the small end, in eighths of an inch at the large end, and the length in halves of an inch.

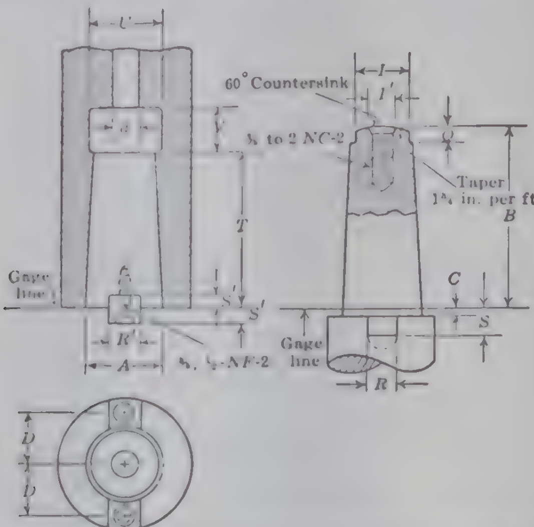

Fig. 13. Taper with key drive and shank retained by drawbolt. See Table 4.

Table 5. Dimensions of Steep Machine Tapers

(ASA B5.10–1943. All dimensions given in inches.)

No. of Taper	Taper per Foot *	Diameter at Gage Line		Length Along Axis

55	3.500	3 1/2	3.500	5 3/16	5.1875
60	**3.500**	**4 1/4**	**4.500**	**6 3/8**	**6.3750**

* This taper corresponds to an included angle of 16° 35′ 33.4″.

The tapers numbered 10, 20, 30, 40, 50, and 60 that are printed in bold-face type are designated as the "Preferred Series." The tapers numbered 5, 15, 25, 35, 45, and 55 that are printed in light-face type are designated as the "Intermediate Series."

MACHINE-PERFORMANCE TESTING

By P. E. Nokes

DEFINITION. Machines on which performance tests are required may be divided into two broad classifications: (1) Machines whose output is power, as such, and whose efficiency is therefore of primary importance. (2) Machines whose output is one of a diversity of articles of manufacture. In these, quality and quantity of product are usually the prime considerations. Power efficiency may be a secondary or even negligible factor.

This chapter will deal entirely with class 2. For performance testing of machines of class 1, see *Power Volume* of Kent's *Mechanical Engineers' Handbook*.

SCOPE OF THE WORK. It is the principal duty of the engineer in charge of performance testing to obtain specific, detailed, and accurate answers to the following questions:

1. Does the machine accurately and consistently perform the operations that are expected of it?
2. Will the machine produce the expected quantity of the product in the specified time?
3. Will the machine and its component parts have a reasonable life expectancy? Are expendable parts of low enough cost and easy to replace?
4. Is the machine properly safe for a person to operate?

Should the answer to any of these questions be "no," the performance test engineer must supply reasons and sufficiently detailed data to aid in correcting the difficulties.

6. METHOD OF PROCEDURE

To evaluate properly the performance of a machine, the test engineer must:

1. Know precisely what the machine was expected to accomplish and in what manner it was expected to operate. These things are by no means always obvious. If specifications are not available or not clear, the engineer may have to write his own, after suitable study.
2. Know in detail the construction of the machine. This should include a thorough knowledge of the expected behavior of all parts, in particular the instrumentalities which actually do work on the article produced.
3. Be prepared to measure and describe the behavior of any part whose performance might be open to suspicion.

In checking over work to be done, a regular procedure may be followed. Below is a check list which will be found to fit the average machine. It may be expanded or contracted to fit special cases. Starting at the point where driving power enters the machine, we have the following:

A. Input (motor—lineshaft belt, or other)
    (1) Power—average—any excessive peaks?
    (2) Speed—is it correct—is it maintained during machine cycle?
    (3) Bearings—excessive temperatures—excessive bearing pressures—lubrication?
B. Input end drive (direct—belts—gears, etc.)
    (1) Has it sufficient power-transmitting capacity?
    (2) Slippage (particularly of belt drives)—is it excessive?
    (3) Flywheel (if present)—is it necessary—is its speed drop during delivery of power reasonable? If not present at all, should a flywheel be used?
    (4) Clutch and brake mechanism—do these bring machine to speed and stop it in specified time—is excessive slip present with machine idling, is any excessive drag present (as evidenced by temperatures reached)—will clutch or brake be adversely affected by oil on surfaces?—are associated mechanisms, such as operating and nonrepeat devices, properly designed and do they perform as intended?
    (5) Bearings—are these in sufficient number and properly disposed—are bearing pressures reasonable—is there adequate provision for lubrication?
C. Machine proper
    (1) Principle of operation—do parts actually perform the service intended—are linkage paths as anticipated—do cams and their associated linkwork give the specified end result?
    (2) Interferences—are there any actual or potential interferences between parts?
    (3) Stresses—any overstressed parts?
    (4) Deformations—are any parts elastically or permanently deformed in service so as to render them unserviceable, or so as to produce undesirable secondary effects?
    (5) Bearing loads and pressures—too great at any point?
    (6) Gear and cam loads (should be given particular attention).
    (7) Lubrication—design of system—adequate supply—proper lubricants—reliability—ease of maintenance and servicing?
    (8) Vibration and noise—present—can they be eliminated?

D. Working instrumentalities (i.e., the parts which work directly on "the product")
  (1) Specific action of each on the product—is the action of each as intended—does each produce the desired result? (Note. Both these questions should be answered; they are not, as might appear, mutually exclusive.)
  (2) Paths of motion of these parts—are they correct?
  (3) Loads, forces, and stresses, in and on these parts—too great in any case—if so, can they be corrected?
  (4) Wear—is this a potential source of trouble?
  (5) Expendable parts—present—have they been made as simple and inexpensive as possible—short life?

To obtain authoritative answers to the questions contained in the foregoing list (revised as necessary), numerous tests must be made, the nature of each of which will be apparent from the question. Since, however, it is almost axiomatic that machines "at speed" do not perform in the same manner as when "turned over by hand," it will be found desirable in most cases to test at actual working speeds, and under as nearly actual service conditions as possible. Static testing will be found to be the exception rather than the rule.

7. TEST EQUIPMENT

The most useful and versatile pieces of apparatus for dynamic testing of machinery in general are the modern electric strain gage set-up and the high-speed motion picture camera. The camera, with its accessories, will cover all cases where the phenomenon, except for speed, could be viewed properly by the eye. The strain gage apparatus will handle almost all cases where instrument observation is necessary.

MOTION PICTURES. In normal motion-picture work, the individual pictures comprising the complete film are taken and projected at the same speed (i.e., same number of pictures or "frames" per second). This number is usually either 16 or 24 frames per second. If a larger number of frames per second is used in taking than in projecting, the motions photographed will appear to be "slowed down" by the ratio of taking speed to projecting speed. For example, if taken at 64 frames per second and projected at 16, motions will be apparently slowed by a factor of 4.

Cameras are available capable of taking motion pictures at as high as 8000 frames per second on 8-mm film, 4000 frames per second on 16-mm film, and about 1200 frames per second on 35-mm film. All these may be projected at 16 frames per second, giving "slow-down" ratios of 500, 250, and 75, respectively. The camera speed is in all cases adjustable.

Cameras are of two general types. In one type (Edgerton, produced by General Radio Corp.) a bank of stroboscopic lamps, synchronized with the camera, provides both illumination of sufficient power and the necessary separation between frames. Its advantage is short exposure time (1 to 10 microseconds) and extreme motion-stopping power. Its disadvantages are first cost and power consumption. A second type of camera (Fastax, by Western Electric, and the Eastman Kodak Company's high-speed camera) depends on a small revolving prism in the optical system of the camera. The prism causes the image to follow the film during exposure. The exposure time of this camera is longer than that of the Edgerton type. It is lower in first cost, however, and uses more conventional illumination. Most mechanical cases can be adequately handled by either type. In both, development and printing of the resultant film follows conventional photographic practice.

Projection equipment is also standard. However, it is well to provide a projector capable of showing single frames and also of being reversed. Reversal (i.e., running the film backward) will, while unconventional, often provide additional information, while projection of single frames allows measurement of the screen image. Such measurements are of great value in obtaining motion paths of machine parts, if care is taken to account for the magnification ratio of the system. A scale included in the original picture will, of course, provide for this point.

If time is an important consideration, it is not possible to depend on film speed in the camera. A clock should be included in the picture. A suitable clock for this purpose may be constructed by placing a properly marked dial directly on the shaft of a small 1800 or 3600 rpm synchronous motor. If great precision is necessary, the motor may be driven, through amplifiers, by a precise tuning fork.

The speed at which pictures should be taken in any case will be governed by the time duration of the phenomenon under observation. During this time, a sufficient number of frames should be exposed to detail the cycle properly without missing essential parts.

Some trial may be necessary to determine both speed and optimum lighting in a particular case.

ELECTRIC STRAIN-GAGE APPARATUS. A complete set-up of electric strain-gage apparatus consists of (for one channel or one measured value) a strain-gage bridge, a power supply for this bridge, an amplifier, and some form of indicating or recording device. This apparatus is shown diagrammatically in Fig. 1.

All the diagram to the right of line *B*–*B* in Fig. 1 constitutes the permanent section of the strain-gage apparatus. It consists of one-half a Wheatstone bridge (adjustable resistances r_1 and r_2), with addition of condenser *C* and switch *S* for balancing cable capacities, oscillator (*O*) for supplying power to the bridge, amplifier (*A*), and, finally, recorder (*R*). This section of the apparatus may be obtained from several sources (General Electric, Hathaway Instrument Co., etc.). Its construction is not within the scope of this chapter. For mechanical testing, however, and as a guide to purchasing, experience dictates that this part of the apparatus should have these characteristics: (1) A frequency range extending from zero to about 1000 cycles per sec. (2) Wide adjustability in amplification. (3) Adaptability to use in simultaneous multichannel form. (4) Produce good-sized legible records. (5) Be provided with an indicating meter for use with slow phenomena and where a permanent record is not required. (6) Be usable with all current forms of electric strain gage.

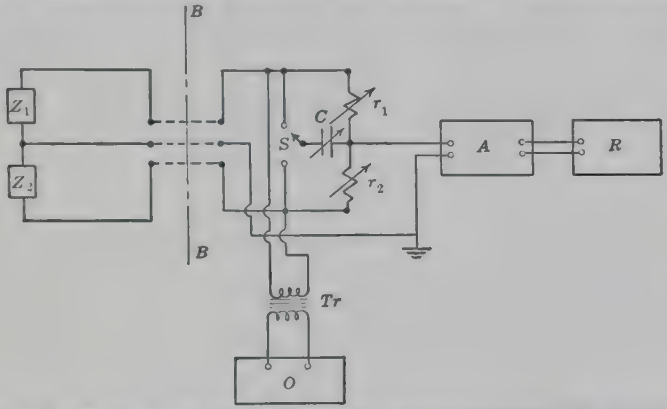

Fig. 1. Strain gages with associated bridge circuit, amplifier, and recorder.

The diagram to the left of line *B*–*B* in Fig. 1 constitutes the sensory element (or elements) of the apparatus and the other half of the strain-gage bridge. It consists of two electrical impedances (resistance, inductance, or capacity) made up, often quite crudely, to suit the job on hand. Either or both may be active gages. If only one is active, the other is present as a "dummy" to complete the circuit and/or to maintain thermal balance. The simplest way to maintain proper balance is, in any case, to make Z_1 and Z_2 physically identical. Since Z_1 and/or Z_2 are the sensory elements, they are, of course, located on or adjacent to the element to be tested. Shielded cable is used to connect them to the permanent part of the apparatus. The two most useful forms of Z_1 and Z_2, namely, resistance and inductance, will be discussed in more detail subsequently.

For the recorder (*R*) of Fig. 1, a multi-element bifilar oscillograph will be found most useful and versatile for mechanical testing. For a detailed description, the reader is referred to any electrical engineering handbook. The device produces a record by moving a light beam over photographic paper or film, which is subsequently developed in the usual manner. The oscillograph may be obtained in a form giving as many as forty-eight simultaneous records, although six or twelve is more usual and will be found most useful for this class of work.

This type of recorder may be used for static, as well as dynamic, work where necessary and is recommended unless no dynamic work at all is contemplated.

The two most useful forms of Z_1 and Z_2, of Fig. 1, are the resistance wire strain gage and the magnetic (or inductance) gage. A more detailed discussion of these forms follows.

RESISTANCE WIRE GAGES. The resistance-wire strain gage is based primarily on the principle that when a wire is stretched, its length increases and its diameter decreases. Both these actions cause an increase in its electrical resistance, and this increase, though small, is detected, amplified, and recorded by the apparatus previously described. A convenient form of the gage (see Fig. 2) may be obtained in various sizes from Baldwin Locomotive Works. It consists of a small piece of thin paper (*a*), to which is affixed, with cement, a grid (*b*) of very small diameter wire (usually 0.001 in.). Larger terminal leads (*c*) are provided to which connecting wires may be soldered. In use, the entire assembly is cemented firmly to a machine part at the desired point, and since its structure is insufficiently stiff to resist, partakes of the surface strain at that point. Stress may be computed from this strain measurement by the usual methods.

Characteristically, the gages are small in size and extremely light in weight. Consequently, they may be affixed in small and relatively inaccessible quarters, and do not add appreciably to the mass of even small parts. The gage is known to follow stress fluctuation to at least 30,000 cycles per sec.

The use of resistance wire gages for the measurement of stress as such is a subject of considerable magnitude and will not be discussed in detail here. References are given at the end of the chapter which discuss the detailed use of the gages for this purpose. This information should be followed in obtaining information on strength of machine frames and parts under working conditions. Other quantities may be measured as follows.

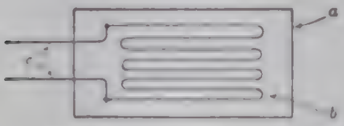

FIG. 2. Strain gage element.

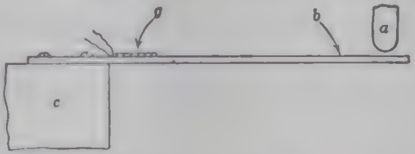

FIG. 3. Application of strain gage to space-time measurement.

Torque and power measurements may be made using resistance wire gages. For this purpose, one or two gages (refer again to Z_1 and Z_2 in Fig. 1) are placed at an angle of 45 degrees on a shaft either existing in the machine or supplied for the purpose. Connections, in this case, are made through slip rings and brushes. A plain brass slip ring, with phosphor-bronze or beryllium-copper brushes will be found excellent. Do not use carbon brushes. Calibration may be obtained most readily by twisting the shaft in a torsion testing machine, although in some cases a spring scale and Stillson wrench will serve. A separate and simultaneous record of speed (see below) will be required to obtain instantaneous power. If desired, compact torque-measuring units of the type described above may be purchased from Baldwin Locomotive Works.

Space-Time Measurements. An excellent device for measuring the path of parts at moderate speeds is shown in Fig. 3. A strip of thin, flat spring stock (*b*) is clamped by some convenient means to machine frame *c*, and allowed to rest against part *a* (the part whose path is to be described). A wire strain gage *g* forms either Z_1 or Z_2 of Fig. 1. Calibration is obtained by moving part *a* slowly and making measurements with a rule or micrometer.

Pressure Measurement (hydraulic or pneumatic). Devices for this purpose, using wire-strain gages, may be purchased or may be constructed as shown in Fig. 4. A flattened piece of thin-walled tubing, closed at the outer end, is soldered to a standard pipe fitting of suitable size. A wire-strain gage is cemented around the tube at *g*. This gage is again Z_1 of Fig. 1. If temperature compensation is necessary, a gage at *g'* or some other unstressed part of the system forms Z_2 of Fig. 1. This device may be varied in range by varying wall thickness of the tubing; and for pressures above about 500 psi, the tube need not be flattened. A suitable calibrating system consists of a hand pump and a conventional pressure gage of good quality.

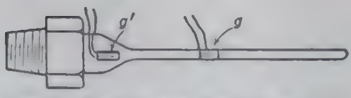

FIG. 4. Strain gages applied to pressure measurement.

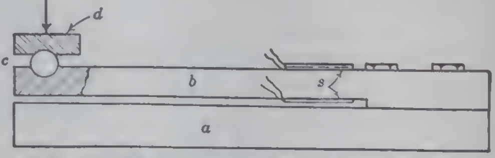

FIG. 5. Device for measuring force transmitted by a machine to the floor.

Force. The force exerted by or on a machine part may often be measured by determining the stresses existing in the part or in adjacent parts. The case exists, however, in which it is necessary to know the force exerted externally by the machine on some object. A case in point is the dynamic force transmitted by the machine to the floor on which it stands. This can be done advantageously by supporting the machine on a suitable number of devices as shown in Fig. 5.

To a steel base plate (*a*) is bolted a stiff cantilever beam (*b*). A large ball-bearing ball (*c*) transmits load from pad *d* (fixed to the machine). A pair of wire-strain gages (*s*), affixed to the beam, form Z_1 and Z_2 of Fig. 1. The device is calibrated in a conventional testing machine. The device must, of course, be proportioned to support the weight of the machine plus any expected dynamic loads, and should be as stiff as possible in order to avoid changes in transmission characteristics due to spring loading.

Acceleration. Rather simple devices are available for measuring acceleration if the curve representing it is periodic and of essentially sinusoidal form. Such conditions exist in vibration measurements. The more usual case, in machine testing, is the one in which the acceleration is nonrepetitive and is complex in form. In this case, such approaches are useless, and, if possible, acceleration should be deduced from force and mass considerations, force being measured as previously described. If direct measurement is desired, a small cantilever beam erected on the part whose acceleration is to be measured may be equipped with wire-strain gages, and the stress therein used as a measure of acceleration. Considerable care must be used in design, as the basic vibrational frequency of the cantilever must be several times (say five) the highest frequency to be recorded. An enclosure to contain damping oil may be necessary. For large accelerations, a tension rod may advantageously be substituted for the cantilever. Several commercial embodiments of the above apparatus are currently appearing.

MAGNETIC GAGES. Impedances Z_1 and Z_2 of Fig. 1 may be inductances instead of resistance as in the wire gage. An inductance for this purpose consists of a coil of wire wound on an iron or steel core. The prototype of these gages, for use with a strain gage setup, is shown in Fig. 6. It consists of an iron core (*a*), with a thin air gap at *b*, and a coil (*c*). The phenomenon under test is in some fashion caused to vary the width of air gap (*b*), thus varying the inductive impedance of the coil. This coil, and an identical one for balancing, form the impedances Z_1 and Z_2 of Fig. 1.

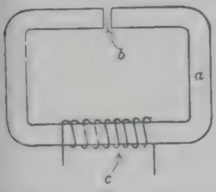

FIG. 6. Elementary magnetic gage.

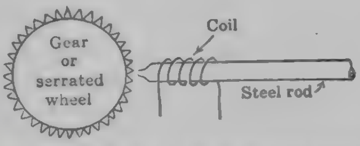

FIG. 7. Device for instantaneous speed measurement.

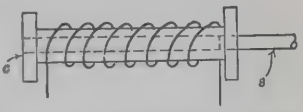

FIG. 8. Application of magnetic gage for measurement of linear motion.

Gages of this type, specifically adapted for strain measurement, may be obtained commercially (General Electric Co., Hathaway Instrument Co.) and may in some cases be extended to measure other quantities. A discussion of other specific types for various purposes appears below.

Speed Measurements. An excellent device of the inductive impedance type for the measurement of rpm may be constructed as in Fig. 7. A ferrous metal gear or serrated wheel (it may be part of the machine under test) has a steel rod with chisel-pointed end arranged to just clear its teeth. On this rod is wound a coil which forms the impedance Z_1 of Fig. 1. The coil may have about 500 turns. Wire size is not important. The device produces an oscillograph record containing one peak for each tooth of the wheel. In conjunction with a timing wave on the record, it will yield information on rapidly varying angular velocities. The number of teeth in the wheel may vary, depending on the detail desired. The device is simple and inexpensive for measurement of such factors as clutch slippage and the like.

Space-time Measurements. For the measurement of small, rapidly varying dimensions such as shaft deflection and "whip" under working conditions, the steel rod and coil combination of Fig. 7 may again be used. The rod end is arranged to just clear the shaft or other piece as it rotates. Shaft deflection appears as a steady signal, while "whip" produces a repeated wave, often a sine function.

Large Motions. Figure 8 shows an apparatus for the study of larger motions under working conditions. A steel rod (*s*) is allowed to move through a coil wound onto a preferably nonmetallic core (*c*), which may also serve as a guide for the rod. Either coil or rod may move in response to the motion under examination, and may be of any length desired. The signal is quite linear, only provided the rod end is not allowed to approach too close (say 1/8 in.) to either end of the coil at the limits of its motion.

Calibration and Balancing. The usual method of obtaining a balance between Z_1 and Z_2 of Fig. 1 for inductance gages consists of providing two almost identical parts and coils, one used for Z_1 and one for Z_2. Either may be the active gage. Since, in the usual strain-gage amplifier, no provision is made for inductive balance, it is necessary first to make a resistance and capacity balance, then remove or add turns to one of the coils until a balance is obtained. Resistance and capacity balance are finally corrected to obtain a balance of the whole system.

Since all these devices read statically or dynamically, calibration may be obtained by means of feeler gages, micrometer, or rule, as suits the case.

OTHER DEVICES FOR STRAIN-GAGE APPLICATION. The foregoing paragraphs on the use of the strain-gage oscillograph combination gives only the general picture, plus a few of the useful measuring devices with which it may be used. With a little experience, many more (particularly special ones) will suggest themselves to the test engineer. The principles shown above may be extended indefinitely. A careful perusal of the references at the end of this chapter will also show many applications.

STROBOSCOPES. The stroboscope, like the high-speed motion picture camera, is used for the direct observation of fast-moving mechanisms. Its use, however, is confined to mechanisms whose motions repeat themselves at least eight or ten times per second. In principle, the stroboscope allows the eye periodically a very short-time view of the object under observation. If, for example, the eye is allowed exactly one look per revolution of a rotating part, the part will appear stationary. Obviously, the period of observation must be synchronized in some manner with the periodicity of the mechanism, while the observation period must be sufficiently brief so that the mechanism does not move appreciably during this time.

Commercial stroboscopes may be obtained in two types:

1. A rotating shutter type, in which a shutter, often clockwork driven, is held before the observer's eyes. Adjustment of speed is provided for synchronization. This type affords excellent portability (one type will fit in a coat pocket), but the length of exposure gives some blur to the field. Some of these devices are speed calibrated for use as observational tachometers.
2. The flashing light type, of which excellent examples may be obtained from the leading electrical manufacturers. These are based on the periodic production of a brief, intense flash of light. Since the duration of flash may be as short as a few microseconds, definition is excellent. Some are driven by adjustable calibrated oscillators and may be used as tachometers. Usually, a contactor mechanism is provided to allow synchronization from the machine under observation.

Some care is required to obtain accurate observations and speed readings with a stroboscope. If the periodicity of the phenomenon under observation is n per second, stationary images will also be obtained with $2n$, $3n$, etc., observations per second, although these will be double, triple, etc., images. Likewise, synchronization will be obtained with $\frac{1}{2}n$, $\frac{1}{3}n$, etc., observations per second, and the images will be natural (i.e., not double, triple, etc.). Practice will show that the last synchronization before a double image appears is the fundamental and correct one. An excellent practice object is a revolving white cardboard disk with one black spot on it.

DYNAMOMETERS

Dynamometers are instruments used for measuring power. They are of several classes: (1) Traction dynamometers, used for determining the power required to pull a car or other vehicle, or a plow or harrow. (2) Brake or absorption dynamometers, in which the power of a rotating shaft or wheel is absorbed or converted into heat by the friction of a brake or into electrical energy. (3) Transmission dynamometers, in which the power in a rotating shaft is measured during its transmission through a belt or other connection to another shaft, without being absorbed.

TRACTION DYNAMOMETERS generally contain two principal parts: (1) A spring or series of springs, through which the pull is exerted, the extension of the spring measuring the pulling force. (2) A paper-covered drum, rotated either at a uniform speed by clockwork, or at a speed proportional to the speed of the traction, through gearing, on which the extension of the spring is registered by a pencil. The average height of the diagram above the zero line gives the average pulling force in pounds. This multiplied by the distance traversed, in feet, gives the work done, in foot-pounds. The product divided by the time in minutes and by 33,000 gives the horsepower.

ABSORPTION DYNAMOMETERS may be mechanical, hydraulic, or electrical. Power developed is wasted in the process of measuring, usually by conversion into heat which must be dissipated.

The Prony brake is the typical form of absorption dynamometer. Primarily this consists of a lever so connected to a revolving shaft or pulley that the friction induced between the surfaces in contact will tend to rotate the arm in the direction in which the shaft revolves. This rotation is counterbalanced by a weight-measuring apparatus, as a platform scale, one or more spring balances, or simply by weights hung in a pan at the end of the lever arm attached to the friction surfaces. (See Fig. 1.) The friction blocks *B* are of wood, and are confined by the strap which can be tightened on them, to increase the friction on the wheel, by means of the bolt *C*. The lever *D* is bolted to the band *A* and bears on the scale as shown. The heat generated by the friction is carried off by water introduced inside the rim, and removed by the outlet pipe which is shaped so as to scoop the water from the rotating wheel. Alternatively, the water may be allowed to evaporate, the outlet scoop being eliminated. The downward pressure of the lever arm is balanced by the weights *W* on the platform scale.

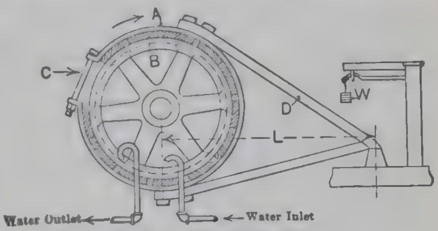

FIG. 1. Prony brake.

If L = horizontal length of lever arm, feet; N = rpm of wheel; W = weight required to balance the downward pressure of the lever arm, pounds; w = tare of brake, pounds, = weight on scales with apparatus at rest; and Hp = the horsepower of the shaft or mechanism to which the brake is attached,

$$\mathrm{Hp} = \frac{2\pi LN(W - w)}{33{,}000} = \frac{(W - w)N}{K} \tag{1}$$

where $K = 33{,}000/2\pi L$. If $L = 33/2\pi = 5\ ^1/_4$ ft (approx.), $\mathrm{Hp} = (W - w)N/1000$.

If the rubbing surface is too small, the resulting friction will show great irregularity; probably because of insufficient lubrication, the blocks will seize the pulley and thus produce shocks and sudden vibrations of the lever arm.

Soft woods, as bass, plane tree, beech, poplar, or maple, are to be preferred to the harder woods for brake blocks. The blocks should be spaced at least $^1/_4$ in. apart. The rubbing surface should be well lubricated with a heavy grease.

Another form of Prony brake is a pair of blocks or jaws, gripping the shaft. The blocks should extend around the greater part of the circumference. A pair of bolts through the blocks on either side of the shaft serves to tighten the blocks on the shaft. A lever arm of any desired length is attached to the upper block and bears on a platform scale or is supported by a spring balance. The horsepower is computed by eq. 1.

Rope Brake. For small amounts of power, the Prony brake may consist simply of a rope or strap wrapped around the brake wheel, one end being fastened to the floor or some other immovable part of the structure, through a spring balance, and the other end attached to a second spring balance or weighted. (See Fig. 2.) If W and w are, respectively, the net applied weight and the net spring balance reading and R is the radius of the brake wheel in feet,

$$\mathrm{Hp} = \frac{2\pi RN(w - W)}{33{,}000} \tag{2}$$

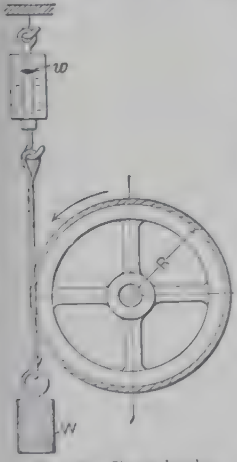

FIG. 2. Rope brake.

Prony brakes are suitable only for the measurement of relatively small powers, say up to about 100 hp and for speeds of not over 1000 rpm. For greater horsepower and higher speeds, a water brake or electric dynamometer should be used.

Capacity of Friction Brakes. W. W. Beaumont (Ref. 1) deduced a formula by means of which the relative capacity of brakes can be compared, based on the amount of horsepower ascertained by their use.

Let W = width of rubbing surface on brake wheel, inches; V = velocity of point on circumference of wheel, feet per minute; K = coefficient; then

$$K = WV \div \text{Hp} \tag{3}$$

Professor Flather recommends the following:

Water-cooled brake, noncompensating, $K = 400$
Water-cooled brake, compensating, $K = 750$
Noncooling brake, with or without compensating device, $K = 900$

F. A. Halsey (Ref. 2) advised a minimum brake-drum surface for water-cooled Prony brakes of 0.09 sq ft per brake horsepower to avoid the danger of the blocks taking fire.

The Alden absorption dynamometer (Ref. 3) is a friction brake capable in moderate sizes of absorbing large powers with unusual steadiness and complete regulation. A smooth cast-iron disk is keyed on the rotating shaft. This is enclosed in a cast-iron shell, formed of two disks and a ring at their circumference, which is free to revolve on the shaft. To the interior of each of the sides of the shell is fitted a copper plate, enclosing between itself and the side a watertight space. Water under pressure is admitted into each of these spaces, forcing the copper plates against the central disk. The chamber enclosing the disk is filled with oil. To the outer shell is fixed a weighted arm, which resists the tendency of the shell to rotate with the shaft, caused by the friction of the plates against the central disk.

Hydraulic Brakes. The usual type of hydraulic or water brake consists of a rotor keyed to the shaft and rotating in a casing filled with water. Power absorbed heats the water, which is circulated at such a rate as to prevent boiling. Torque resistance is controlled by varying the quantity of water in the casing.

For measuring power at high rotational speeds the rotor may consist simply of a disk or series of disks. For medium and low speeds the disk usually is provided with vanes or pockets to increase the drag by promoting turbulence. For formulas and design details for this type of brake, see E. P. Culver (Ref. 4).

Reaction torque on the casing may be determined by any of the usual methods of weight measurement. Alternatively, the torque may be set by placing a predetermined weight on the lever arm and providing automatic control of water flow, as described in the reference just cited.

Hydraulic dynamometers are commercially available in sizes ranging from small capacities up to several thousand horsepower.

Fan Brakes. For relatively high-speed power measurement a fan, propeller, or "club" may be attached to the revolving shaft. Air resistance to blade motion provides the load, which is determined by measuring the torque reaction at the motor or engine. The method requires mounting the motor or engine on a torque stand which permits it to revolve freely so that the torque reaction may be determined accurately. Alternatively, a fixed mounting and a calibrated fan may be used, for approximate measurements.

Electric Dynamometers. This type of dynamometer is basically an electric generator cradle mounted so that the stator is free to turn about the axis of the shaft. Torque reaction on the stator is measured by beam scales or other convenient means. Electric power which is generated may be dissipated in load resistors consisting of metal wire rheostats or, for larger powers, water rheostats.

By operating the dynamometer as an electric motor, "motoring" tests may be run for determining friction in a machine, or the power absorbed by any type of driven machine such as a lathe. While cradle mounting permits precise, direct measurement of torque, a generator without it may be made to serve, with less accuracy, by calibrating its output kilowatts (or input when motored) in terms of input (or output) power at various speeds and loads.

Eddy Current Brake. A simple type of electrical dynamometer is the eddy current brake, which consists of a disk revolving in a magnetic field. Resisting torque is controlled by varying the field strength, as in the generator type, but there is no current output, the eddy currents being dissipated in the disk, which must be cooled by air circulation if not by other means.

TRANSMISSION DYNAMOMETERS are used where power must be measured under service conditions, as in a ship at sea or an airplane in flight or a machine tool performing its function.

Torquemeters measure the angle of twist in a calibrated length of shaft or some form of flexible coupling through which power is being transmitted. Inasmuch as the twist is usually relatively small, mechanical, optical, or electrical means are employed to magnify the indication. To simplify measurement, some torque meters measure the twist at only one instant during the shaft rotation, which is satisfactory only if the torque is unvarying

If pulsations are present in the torque of either the driving or driven machine, a continuous torque record or an integrated reading is required. Electric strain gages (see Article 7 in this section) are being used for this purpose, among other devices, and there are many types of instruments commercially available.

Belt dynamometers provide a simple means of measuring power transmitted to a belt-driven machine. Essential characteristics are illustrated in Fig. 3. Either flat belts or double-vee belts may be employed, and the principle can also be applied to roller chain drives. Torque reaction on the cradle which carries the idler sheaves is proportional to the difference in belt tension in the tight and loose sides.

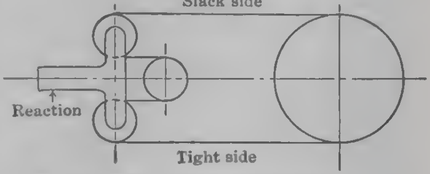

FIG. 3. Elements of belt dynamometer.

Gear Dynamometers. Any type of gear box which reduces, increases, or reverses the speed between input and output shafts produces a torque reaction equal to the algebraic difference between input and output torques. By cradle mounting the housing in anti-friction bearings and measuring the torque reaction a useful form of transmission dynamometer is obtained. Such a measuring device may be incorporated in a complete machine; for example, the stationary sun gear in many aircraft engine planetary reduction units is so mounted, the torque indications being transmitted hydraulically to the cockpit instrument. By feeding speed and torque to an integrator, horsepower may be indicated or recorded direct.

Electric Transmission. Where power is transmitted electrically, as in a diesel-electric locomotive or ship, measurement of the electrical power furnishes an indication of the power developed by the prime mover or absorbed by the driven machine. Electrical losses in the generator and motor at various speeds and loads must be known for calibration purposes.

Hydraulic Transmission. As with electrical transmission, hydraulic power transmitted between a pump and fluid motor may be determined, though less readily, by measuring rate of flow and pressure change.

THERMOMETERS AND PYROMETERS

By Robert B. Sosman

A thermometer is a device intended for the measurement of temperature. **A pyrometer** is a thermometer intended for use principally at temperatures above the first visible "red heat," which is about 500 C or 930 F.

The commonest type of thermometer is the liquid-in-glass type. When the liquid is mercury, the thermometer can be used industrially from −35 C to about 400 C (−30 F to 750 F), whereas with special glasses and a filling of nitrogen under pressure above the mercury, the range can be extended to about 500 C (930 F). Alcohol and liquid hydrocarbons serve for very low temperatures.

The expansion of a liquid in a metal container in place of a glass container gives a less fragile thermometer, though with essentially the same ranges as stated above. The change of volume is commonly registered by means of a Bourdon gage, and this device is also much used with thermometers which depend on the change of pressure of a gas in a metal bulb or on the change of vapor pressure of a liquid contained in such a bulb.

Resistance thermometry, depending on the change in electrical resistance of a wire, preferably of a pure and reproducible metal such as platinum, extends the range into the pyrometer field, to about 1000 C (1830 F), and is also usable to very low temperatures.

The thermometer of widest range is the thermoelectric, covering, with various thermocouples, all temperatures from −200 to 1650 C or from −330 to 3000 F. It stands first in versatility among the three principal types of industrial pyrometer. The other two are the radiation type (including the photoelectric) and the optical type. The radiation instruments are useful mainly, and the optical pyrometer entirely, in the pyrometric field, above 500 C.

THERMOELECTRIC PYROMETRY. The thermoelectric pyrometer consists of three parts: (1) thermocouple, (2) extension wires, and (3) apparatus for measuring the electromotive force of the thermocouple.

The Thermocouple. Take two pieces of wire, *A* and *B*, of different composition; weld one end of *A* to one end of *B*, and the other end of *A* to the other end of *B*, so that a continuous piece of wire is produced. This piece of wire is a thermocouple.

Note particularly that the piece of wire is a complete electric circuit. At every weld or junction between two dissimilar metals in such a circuit an electromotive force is generated. If both junctions are at the same temperature, the emf's will be equal and opposite, and no current will flow in the wire. But make one junction hotter than the other, and there is a net emf which is capable of causing a current to flow around the circuit. If one junction, which we may call the *cold junction* or, better, the *reference junction*, is held at a constant temperature, it is evident that the emf in the circuit can be used as a measure of the temperature of the other junction, the *hot junction* or *measuring junction*.

The Meter. The simplest method of measuring the emf is to cut the thermocouple at any point in its circuit and insert a current-measuring device such as an ammeter or a millivoltmeter (which is essentially a current measurer). The indication of the meter will then depend on the difference in temperature between the two junctions and, unfortunately, also on the total electrical resistance in the circuit, including both thermocouple and meter, in accordance with Ohm's law. Because the reading does depend on the resistance, and also because of certain deficiencies of moving-coil instruments under the severe conditions met with in industrial plants, the millivoltmeter type of instrument has been replaced in many installations by the potentiometer.

The potentiometer, in its fundamental form, balances a known and measured emf against the unknown emf in the thermocouple circuit, and its readings are consequently independent of resistance. Originally used as a hand-operated indicator only, the potentiometer has been made completely automatic in operation, and a number of types of the instrument are now available.

The earlier types of automatic potentiometer utilize a galvanometer and detect its departure from a balanced position by mechanical means. More recent types convert the unbalance of emf into some form of periodic or alternating current and utilize electron tubes for its amplification. These electronic instruments are faster than the mechanical but introduce the difficulties that are peculiar to electron tubes.

Extension Wires. We have been assuming that the thermocouple was cut at some point in order to insert the millivoltmeter or the potentiometer. Suppose the measurement is wanted at a place some distance away. A pair of copper wires leading off to the panel board where the instrument is placed would serve the purpose provided the two ends of the cut remain identical in temperature, and provided furthermore that the reference junction remains actually at a constant temperature. But the prevailing custom is to let the reference junction shift for itself, rising and falling in summer and winter, while its variations are compensated for by some device in the millivoltmeter or the potentiometer. This means that the reference junction must be placed at the instrument. Now some thermocouple materials capable of withstanding high temperature, such as platinum, are too expensive to be used in lengths of hundreds of feet in order to reach a distant instrument. This difficulty is taken care of by extension wires, consisting of a pair of wires of relatively inexpensive alloys which have approximately the same curve of emf against temperature (referred to some average air temperature for the reference junction) as the thermocouple itself. The thermocouple may now be cut open at the reference junction, and the pair of extension wires inserted in the proper direction, whereby the reference junction is transferred effectively to the far end of the extension wires where the meter is to be inserted.

Compensation for temperature change at the instrument must now be provided. In the millivoltmeter type a spring can be used whose elasticity changes with temperature in such a way as to balance the effect of the change in emf produced by the change in temperature of the reference junction. In the potentiometer, the compensation is electrical instead of mechanical. A resistance coil is inserted in the potentiometer circuit, of the proper material and resistance so that, as it warms or cools, its effect on the balancing emf is just equal and opposite to the change in emf produced by the change in reference junction temperature. For the highest accuracy, however, it is best to control the temperature of the reference junction, as by immersing it in a mixture of ice and water.

The foregoing picture of the thermocouple as a complete circuit has been adopted here in place of the customary picture of a pair of wires with free ends, with the deliberate purpose of emphasizing that no thermocouple can function without at least two junctions, one of which is just as important as the other.

The choice of instrument depends on local conditions. The principal advantages of the millivoltmeter are low cost and small bulk; in most other respects, including accuracy and dependability, the potentiometer is preferable.

The instrument may be given any or all of three functions: (1) to indicate the temperature on a scale; (2) to record the temperature either by a continuous curve or by a series of marks on a chart (the chart may be either circular or a continuous strip of paper); and (3) to control the source of heat by way of relays, valves, switches, and the like.

Thermocouple Materials. Three types of thermocouples are in current industrial use: (1) iron-constantan, (2) Chromel-Alumel, and (3) platinrhodium-platinum. (In each case the wire which is positive at the colder junction is named first in the pair.) The iron-constantan couple is used up to temperatures where the iron wire oxidizes away; at 750 C (1400 F) No. 8 iron wire will last about 1000 hr. Chromel-Alumel can be used to about 1200 C (2200 F), but oxidizes away too rapidly at higher temperatures. The platinum combination can be used at all temperatures up to the melting point of platinum at 1773 C (3223 F), although the susceptibility of platinum to contamination at high temperatures usually limits its use to about 1650 C and lower. It is the only couple available for continuous use at temperatures above 1200 C in air.

Chromel and Alumel are proprietary nickel alloys. All the Chromel and Alumel wire used in the United States is made by one manufacturer and is made to exact specifications with respect to thermal emf. The emf-temperature curve of the Chromel-Alumel couple has been standardized by the National Bureau of Standards, and all of the eight or ten instrument makers who furnish industrial pyrometers now use the same emf curve.

The platinrhodium-platinum thermocouple is made in two types. Both use pure platinum as one wire, while the platinrhodium alloy contains either 10% rhodium to 90% platinum, or 13% rhodium to 87% platinum. Standard curves for both these thermocouples have been determined by the Bureau of Standards and are now in general use.

Constantan is made in several compositions by different manufacturers. The iron of the iron-constantan couple is not the pure metal but is a low metalloid steel or "ingot iron." It likewise comes from several different sources. The iron-constantan couple has therefore not been standardized as to composition or emf-temperature curve.

The thermoelectric pyrometer is adaptable, without essential change, to any temperature below 500 C (930 F) in downward extension of its more commonly used range above 500 C. It can be used even at the temperature of liquid air. For these purposes copper-constantan can be used as the thermocouple, with a standard table available which can always be matched with commercially obtainable constantan and pure copper.

OPTICAL PYROMETRY. Although much less used than the thermoelectric pyrometer, the optical pyrometer is essential for temperatures of objects that can be seen but are not easily reached; for example, the tapping and pouring temperatures of steel. To the physicist, the optical pyrometer is a photometer, an instrument for measuring the brightness of a source of light. The brightness of a hot surface, however, is not alone dependent on its temperature but also on its emissivity, and the optical pyrometer consequently can not read temperature directly, except in the single instance of the "blackbody." The best example of a blackbody is a small opening through the wall of a furnace so uniformly heated in the interior that no details can be seen by observation through the opening. On all other objects the optical pyrometer reads a brightness temperature which must be interpreted by a knowledge of the emissivity. The brightness temperature of the flat surface of a reproducible material, such as low-carbon steel, fortunately, does bear a fixed relation to its true temperature, and the optical pyrometer is therefore a reliable instrument for the reproduction of heating, rolling, welding, and finishing temperatures. It is capable of very high precision, especially at the highest temperatures, but the readings are subjective, being dependent on the eye and the judgment of an individual observer. An impersonal check of the reading is therefore not possible.

RADIATION PYROMETRY. The total radiation pyrometer, often called simply the *radiation pyrometer*, measures energy rather than brightness. Its receiver absorbs all the energy radiated from a certain area of a hot surface, both the visible radiation and the heat radiation which at industrial furnace temperatures constitutes the greater part of the energy.

The energy is absorbed in a group of tiny thermocouples connected in series, whose emf thus becomes a measure of the temperature of the radiating source. Like the optical brightness of a surface, its energy radiation is not dependent solely on its temperature, as can easily be observed by holding the hand near a heated black surface and a polished reflecting surface at the same temperature. The polished surface has a much lower emissivity and feels correspondingly cooler, if not touched.

Although the emissivity for total radiation of a sheet of metal coated with a thin adherent film of oxide is less than the emissivity of a true blackbody, it is nevertheless reasonably constant. This fact is bringing the total radiation pyrometer into increasing use for the routine measurement of surface temperatures in the open. Sighted on metal inside a furnace it may give false results because of reflection of heat coming from walls and roof. Sighted into a tube with closed end, it can serve as a controller of furnace temperature, and has the advantage over the thermoelectric pyrometer that there are no wires exposed to contamination and oxidation. The total radiation pyrometer is not well adapted for use as a portable instrument. The receiver is best mounted in a fixed position, and should be provided with air cooling or water cooling if the place is unusually hot.

The same types of electrical instrument (millivoltmeter, automatic potentiometer) are used with radiation and photoelectric receivers as with thermocouples, and they are adaptable to the same functions of indicating, recording, and controlling.

PHOTOELECTRIC PYROMETRY. A special type of radiation pyrometer utilizes the photoelectric cell as a receiver of energy. This type has been coming into use in industrial plants, particularly for high-speed pyrometry, as in the measurement of the brightness temperature of steel strip, rod, and tube. The photocell may be either of the electron-tube type or the self-generative (barrier layer or Photronic) type. It is not a substitute for the optical pyrometer because it exercises no judgment as to brightness. It merely takes from a defined surface that part of the radiant energy which can produce a photoelectric current, and is therefore best classified as a partial radiation pyrometer. Since the current is extremely small, some form of amplification must be used, and care must be taken with electrical leakage. The indicating, recording, and controlling instruments, however, are otherwise no different from those used with the thermoelectric and total radiation pyrometers.

PYROMETER CALIBRATION AND MAINTENANCE. Thermocouples, pyrometer lamps, potentiometers, and similar physical apparatus are always subject to deterioration, particularly under the severe conditions of dust, high temperature, and vibration which are unavoidable in many industrial plants. An essential feature of the pyrometric equipment of the up-to-date plant is, therefore, its pyrometric laboratory for calibration and maintenance of the instruments. The plant with heavy demands on its pyrometric equipment cannot afford the frequent interruptions incident to sending pyrometers to a central calibrating station, such as the Bureau of Standards, nor can it afford the risk of spoilage incident to neglecting its pyrometric equipment for weeks at a time. The larger plants make up their own thermocouples from tested stocks of wire; calibrate the couples either by comparison with standards or by measuring the freezing points of samples of standard metals, such as tin, zinc, and copper; check the accuracy of recorders, controllers, standard cells, millivoltmeters, and milliammeters by means of portable testing sets; check optical pyrometers at frequent intervals against a standard source of brightness; and check total-radiation pyrometers by simultaneous readings on the same surface with a calibrated optical pyrometer. For small plants that cannot afford their own pyrometric laboratory, pyrometric calibrating and maintenance services are available in the larger industrial centers.

GENERAL CONSIDERATIONS. It must always be kept in mind that a thermocouple measures only the temperature of its own hot junction, and an optical, photoelectric, or total-radiation pyrometer measures the average apparent surface temperature of the objects seen by the instrument. For example, a thermocouple may be inserted into a flue with the hope that it will measure the temperature of the passing gas. What actually happens is an approach to an equilibrium between heat supplied by the gas, heat conducted away along the wires and protection tube, and heat radiated to or from the colder or hotter walls of the flue. The resulting temperature of the hot junction is seldom the temperature of the gas. In heat-treating operations on metals, it is not sufficient that the hot junction of the thermocouple is inside the furnace; it should be as near as possible to the piece of metal being treated. A study of the environment and the exercise of good judgment in placing the pyrometer are just as important as the proper selection and maintenance of the instruments.

CALCULATING DEVICES

By W. J. Eckert

Calculating devices fall into two distinct classes, depending on the basic principle of operation, called digital and nondigital. Digital calculators (Ref. 1) employ the basic principle of counting discrete units. The nondigital devices (Ref. 2) depend on the measurement of a physical quantity such as length, angle, and electric current. In each class there is a wide range in size and complexity extending all the way from desk devices to the large central installations.

With the digital devices which depend on counting there is no limit to the precision which may be attained, whereas those which depend on measurement can be no more accurate than the measurements involved. On the other hand, a solution obtained on a digital device is a discrete solution, whereas the nondigital machines usually facilitate the investigation of a solution over a wide range of the quantities involved. Generally speaking, the nondigital devices are more specialized in their application.

8. DIGITAL CALCULATORS

Digital machines perform one or more of the common arithmetical operations, addition, subtraction, multiplication, and division, and sometimes others, such as square root. These operations are combined with the use of mathematical tables.

In the digital method the problem which has been stated in terms of mathematical formulas must be transcribed into a numerical procedure. The numerical processes for interpolation, differentiation, integration, and other mathematical operations are described in standard reference works (Refs. 3, 4, and 5). Since the processes are numerical, a given device will serve for problems from any field.

As an example of a numerical process consider the motion and the acceleration of a knife-edge follower actuated by a rotating cam, where the radius (r) of the cam in terms of the angle of rotation (θ) is given by the following expression:

$$r = f(\theta) = 1 + \sin^2 \theta + E(\theta)$$

$E(\theta)$ is an empirical quantity in the form of a table. The required velocity and acceleration are proportional to ($dr/d\theta$) and ($d^2r/d\theta^2$), which can be evaluated numerically from a table of values of $f(\theta)$ and the differences, δ', δ'', $\cdots$. The values of δ' are obtained from those of $f(\theta)$ by subtracting each one from the following; the values of δ'' are obtained from those of δ', etc.

θ	$E(\theta)$	$\sin \theta$	$\sin^2 \theta$	$f(\theta)$	δ'	δ''	δ'''
0°	0010	0.0000	0.0000	1.0010			
					+0.0030		
2°	0028	0.0349	0.0012	1.0040		+31	
					+ 61		−3
4°	0052	0.0698	0.0049	1.0101		+28	
					+ 89		−1
6°	0081	0.1045	0.0109	1.0190		+27	
					+ 116		−1
8°	0112	0.1392	0.0194	1.0306		+26	
					+ 142		
10°	0147	0.1736	0.0301	1.0448			

The customary formulas for numerical differentiation may be written:

$$\frac{dr}{d\theta} = \frac{1}{\omega} \left\{ [\delta'] - \frac{1}{6} [\delta'''] + \cdots \right\}$$

$$\frac{d^2r}{d\theta^2} = \frac{1}{\omega^2} \left\{ \delta'' - \frac{1}{12} \delta'''' + \cdots \right\}$$

where ω is the tabular interval of θ: $2° = 0.0349$ radian in this case. For any given value of θ, $[\delta']$ is the average of the values of δ' above and below the horizontal line containing θ, and similarly for $[\delta''']$. δ'' and δ'''' are the values on the line. Thus at the point $\theta = 4°$ the velocity

$$\frac{dr}{d\theta} = \frac{1}{0.0349}\left\{\left(\frac{61 + 89}{2} - \frac{1}{6}\,\frac{-3 - 1}{2}\right) \times 10^{-4}\right\}$$

$$= \frac{1}{0.0349}\,\{(75 + 0.3) \times 10^{-4}\} = 0.216$$

and the acceleration

$$\frac{d^2r}{d\theta^2} = \left(\frac{1}{0.0349}\right)^2 \{0.0028\} = 2.3$$

Commercial machines are of two main types, those in which numbers are inserted by means of a keyboard and those which automatically read punched cards.

Printing adding machines are the simplest keyboard machines in general use. Numbers are inserted by means of a keyboard, totals are accumulated in a single register. The individual items and the totals are printed on a paper ribbon. These machines may be electric or hand driven. Some are limited to addition only, and others handle positive and negative numbers. Printing adding machines are also available with more than one adding register; the more complicated of them are called bookkeeping machines. Some of them have a movable carriage so that results may be printed in several columns. A programming device may be attached to the carriage so that the position of the carriage determines the arithmetical and printing operations to be performed.

Desk calculators are equipped with movable adding registers so that they may be used not only for addition and subtraction but for multiplication and division as well. These machines have a wide range of complexity. In some of them the arithmetical operations must be controlled largely by the operator; in others they are highly automatic. The results must be read from dials.

Punched card machines read and record the numbers as punched holes on cards. The machines read these holes and perform the prescribed operations automatically. These operations include rearranging the cards according to the data punched on the cards, printing data from the cards on a sheet of paper or on the cards, transcribing data from one card to another with or without rearrangement of the data, and the arithmetical operations of addition, subtraction, multiplication, or division (Ref. 6). Mathematical tables in the form of punched cards are consulted automatically with as many as 50,000 digits per hour. Punched card machines are of two kinds; those where the operation is controlled mechanically by means of linkages and those where it is controlled electrically by means of relays and plugboards.

Special Calculators. The machines described in the foregoing are all commercially available. In recent years a number of large special machines have been built. The most elaborate of them is an electronic calculator with an internal storage capacity for 400,000 digits, and programming facilities to handle automatically the most complex computational procedures.

9. NONDIGITAL CALCULATORS

The most common nondigital device is the slide rule on which lengths are added or subtracted. They also are available in circular form using angles, including the general numerical variety and also special ones for special fields such as engineering.

The planimeter is a desk device for giving the integral $\int f(x)\,dx$. The function is used in the form of a graph, and the planimeter gives the area under the curve.

Linear Algebraic Equation Solver. Somewhat more elaborate are the devices for such operations as the solution of linear algebraic equations. Examples of them have been made which depend on the measurement of mechanical, hydraulic, electric, and electronic quantities. A common type employs a resistance network where the resistances are set according to the coefficients of the equations to be solved, voltages representing trial values of the unknowns are applied, and the resulting currents represent the amounts by which the equations fail to be satisfied. The operator then adjusts the voltages by inspection until the residual currents become satisfactorily small. At this stage the applied voltages represent the values of the unknowns which satisfy the equations.

Machines of this general type have been built in several forms, depending on (1) the method of input, (2) the method of adjusting the voltage, and (3) the criterion used for adjusting the voltage; in all of them the results are read from an ammeter. Coefficients may be set up on potentiometers or on punched cards. The variables are adjusted by hand or by means of automatic devices. The criterion may be the residual current from a single equation or the sum of the squares of the residuals from all the equations (Ref. 7). An accuracy of 0.1% is reasonable.

The various gun directors and computing sights used during the war are other examples of nondigital devices.

Large central installations include differential analyzers and network analyzers. The differential analyzer is capable of handling the solution of complicated differential equations. Network analyzers are used to investigate power networks.

IRON AND STEEL CASTING

By Charles K. Donoho

1. CAST IRON

DEFINITION AND TYPES. Cast iron is essentially an alloy of iron, carbon, and silicon in which carbon is present in excess of the amount which can be held in solid solution. The maximum amount of carbon which can be held in solid solution in iron at any temperature is usually considered to be about 1.7%. Most cast iron contains 2.0 to 4.0% of carbon. In *gray cast iron* at least a portion of the total carbon content is rejected from solution during freezing in the form of graphite flakes which are interspersed throughout the steel-like matrix. A useful concept of gray iron is that it may be considered to be "steel plus graphite." In *white cast iron* all the carbon is retained in the combined form. The massive iron carbides cause this material to be hard, brittle, wear resistant, but almost unmachinable.

Where cast iron contains specially added elements in amounts sufficient to affect the properties measurably, it is called *alloy cast iron.* Silicon, manganese, sulfur, and phosphorus as normally obtained from raw materials are not considered alloy additions.

USES. The engineering properties of gray iron which determine its uses are largely dependent on its graphite content. The precipitation of graphite from solution during freezing in the mold counteracts shrinkage and makes the metal easier to cast into sound parts than other metals with high shrinkage. As compared to other ferrous metals, the higher carbon content of cast iron enables it to be cast at lower temperatures and in molds of lower refractoriness. Cast iron may be melted in the cupola furnace, which is the most economical method of melting metals. These facts influence the choice of cast iron for a variety of castings and make it the largest tonnage foundry metal.

Where bulk and inertia are important the uses of gray iron castings are well known. Machine-tool frames and bases are cast of gray iron in intricate forms with high accuracy to finished dimensions. In such applications the graphite content increases the useful property of *damping capacity*, which limits vibration set up by moving parts. For services involving *wear*, cast iron is used in motor blocks, piston rings, brake drums, and many types of cylinders and plungers. For services where *corrosion resistance* is important, cast iron is widely used for underground pipe, and also has many applications in the chemical industries. Gray cast iron is more easily *machinable* at a given hardness level than most other metals because the graphite flakes break up the chip formation. For this reason many parts requiring high-speed production machining are cast of gray iron.

There are other large-scale uses of gray iron castings in these fields of application:

For *heat resistance:* grate bars, stove parts, radiators, firepots, and ingot molds.

For *wear and abrasion resistance:* brake shoes, car wheels, rolls, crankshafts, plowshares, plowpoints, wheels, crushers, wear plates, and sludge pumps.

For *corrosion resistance:* pipe, retorts, evaporators, valves, and refining equipment.

For *production machined parts:* automobile parts, washing machines, refrigerators.

For *architectural services:* columns, railings, ornamental work, sash weights, and stair treads.

For *municipal services:* fire plugs, manhole covers, lamp posts, mail boxes, and traffic markers.

PROPERTIES. The physical and mechanical properties of cast iron are varied widely by varying the composition, section size, freezing rate, and thermal treatment. Generally, those factors which tend to increase graphite—high carbon, high silicon, slow freezing—also progressively soften and weaken the iron. Increasing graphite content also confers the properties of easier machining, increased damping capacity, and better resistance to heat shock.

Strength Properties. Gray cast iron may be specified with tensile strengths from 20,000 psi minimum up to 60,000 psi minimum. Strengths of 25,000 to 40,000 psi encompass the majority of regular iron castings. Beam strength or bending strength is conveniently expressed as modulus of rupture. The modulus of rupture of cast iron is 1.5 to 2.5 times the tensile strength, the higher ratios occurring with the lower strength irons. Torsional strength of cast iron, expressed as modulus of rupture in torsion, varies from about 1.2

to 1.4 times the tensile strength. However, torsional and bending strengths of specimens other than circular in section will vary with the specimen shape. The compressive strength of gray cast iron is about 2 1/2 to 4 times the tensile strength, the higher ratios again occurring with the irons of lower strength. (See Fig. 1.)

Hardness. The hardness of cast iron varies from about 120 Brinell in the softest gray irons up to about 600 Brinell for chilled or white irons. Brinell or Rockwell hardness is often specified for gray iron castings, usually as a maximum limit to insure to some extent the degree of machinability. In general, softer irons are easier to machine than hard irons, although there are factors other than hardness which influence machinability to a considerable degree. There is a broad general relation between hardness and strength of gray cast iron although the degree of correlation is not so high as in steel or other more homogeneous metals. Figure 2 shows the relation of tensile strength to Brinell hardness for a large number of commercial cast irons. In general, engineering irons of highest quality fall to the top and left of the field in Fig. 2, i.e., irons with the highest strength for a given hardness. Irons with high tensile-Brinell ratio also tend to be more uniform in structure and better for wear resistance.

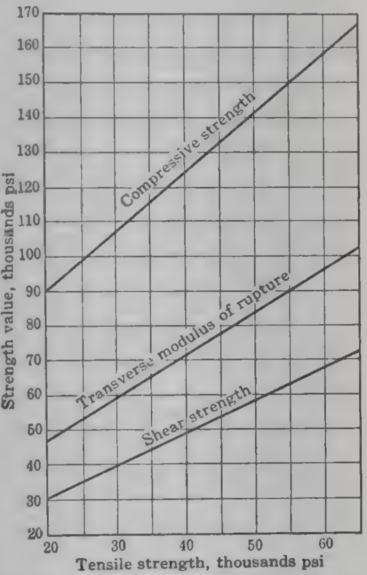

FIG. 1. Idealized chart showing approximate relation of other strength values to tensile strength for gray cast iron.

Impact Resistance. The engineering conception of gray cast iron generally is of a brittle material, incapable of shock or impact resistance. However, gray iron castings are used in many places where knowledge of impact resistance is important, as in pistons for internal-combustion motors and car wheels that are specified and purchased on impact tests.

A far-reaching investigation undertaken by ASTM Committee A-3 on the relation of impact properties to chemical and physical properties of cast iron was completed and reported in 1933. The developed data of the investigation are given in Table 1. Each test includes an investigation of three to six sets of specimens with varying chemical analyses and different types of foundry conditions. Besides impact values, transverse, tensile, and compression tests were made and hardness values established.

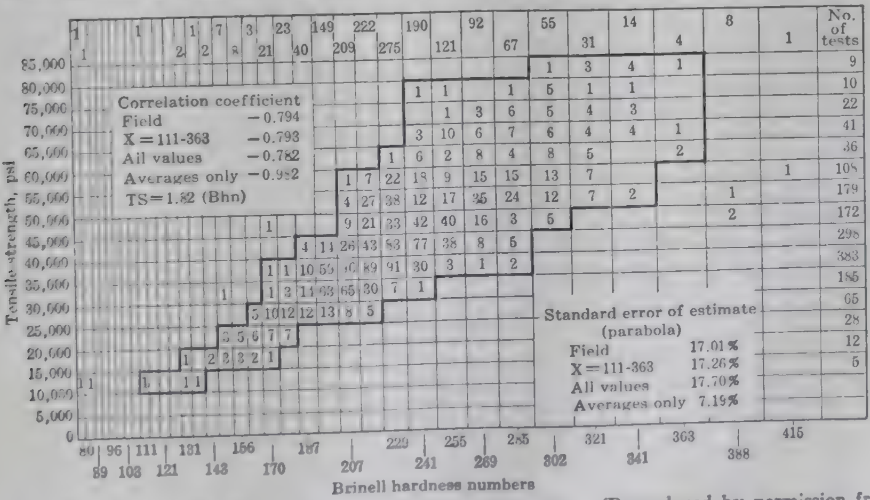

FIG. 2. Data from 1553 Brinell hardness–tensile strength tests. (Reproduced by permission from paper by MacKenzie, *Proc. ASTM*, Vol. 46, 1946)

In Table 1, summarized from data presented, average values are given. Brinell hardness is an average of values taken at the rim, center, and midway on the cross section of test

* Bars cast to 1.4 in. and machined to 1.20 in. diameter. † Mo = 0.07. ‡ Mo = 0.45. § Not suitable for heavy section. ‖ Cu = 4.07; a martensitic iron not commercially used at the time of the investigation. ¶ Not suitable for light section. ** Cu = 6.12, an austenitic iron for high temperature and corrosion resistance.

specimens. The final columns include impact values established on unnotched specimens by the Charpy and Russell pendulum-type testing apparatus, the specimen being supported rigidly near the ends and struck at the center. Three of the columns are variations of the falling hammer test on a specimen 1.20 in. in diameter supported at 6 in., 5 in., and 6 in., respectively. The first of these falling hammer tests used a 25-lb weight from an elevation of 2 in., with increasing increments of $^1/_2$ in. The table gives average height from which hammer dropped when the bar broke. The second of the falling hammer tests was on specimens supported at 5 in. centers with an 11-lb weight starting at 1 in., with increasing increments of 1 in. The third summarizes average tests at 6 in. centers with 25-lb weights starting at 1 in., with increasing increments of 1 in.

The impact test, essentially a measure of energy absorbed in breaking bars, may be expressed by the work done, namely force times distance through which force moves. Results of Charpy and Russell tests are in foot-pounds. The others may be computed from the drop and weight of hammer.

Fatigue Strength. The endurance limit of gray cast iron in repeated stress varies almost linearly with tensile strength, the ratio of endurance limit in reversed bending to static tensile strength usually being between 0.40 and 0.55. An important property of cast iron in fatigue service is its relative lack of notch sensitivity. Sharp notches in cast-iron parts do not affect the endurance limit as seriously as in the more homogeneous metals.

Wear Resistance. Gray cast iron has considerable value as a wear-resistant material for bearings, automobile cylinders, piston rings, and slides on machine tools. The heterogeneous structure with components varying from soft graphite and ferrite to hard phosphides and carbides gives gray iron nongalling and nonseizing properties in the same manner that hard particles in a soft matrix confer wear resistance on bearing metals. Recent studies have shown clearly that the best gray irons for wear resistance have a normal graphite structure in a pearlitic matrix. Irons with interdentritic segregates of fine graphite with free ferrite have relatively poor wear resistance. For some important wear services a micro structure requirement is an important part of the specifications.

For other types of wear service, chilled or white irons are valuable because of the high hardness conferred by massive carbides. Chilled railway-car wheels and chilled camshafts are examples of their class. Martensitic white irons alloyed with nickel and chromium are often used for severe wear service where the very high degree of hardness is desirable.

Corrosion Resistance. Gray iron does not deteriorate rapidly under normal corrosive conditions. Cast-iron pipe for underground service, cast-iron kettles, retorts, and evaporators are examples of iron castings used for corrosion resistance. The graphite particles in cast iron are quite noble and noncorrodible, and phosphides are also corrosion resistant. When cast iron corrodes on the surface, the corrosion products tend to remain firm and intact, preventing or reducing subsequent attack on the underlying metal.

There are several valuable corrosion-resistant special cast irons. Cast iron with about 15% silicon makes a rather brittle, unmachinable white iron with remarkable resistance to most chemicals and all strong acids except hydrofluoric and hot, concentrated hydrochloric acid. Gray irons made austenitic by high percentage additions of nickel, copper, and chromium have many times greater resistance in most corrosives than unalloyed iron or steel.

Heat Resistance. Some engineering codes established more than thirty years ago limited the use of cast iron to temperatures of 450 F where pressure is also involved. According to a study by Burgess and Barlow (*American Foundryman*, May 1945), properly controlled gray iron can be successfully employed in pressure service at temperatures up to at least 750 F. Best heat resistance is found in gray irons with carbon equivalent, % C plus 0.3 (% Si + % P), in the range of 3.4 to 3.9. Unalloyed irons with a carbon equivalent of 4.0 or greater normally are not suited for high-temperature pressure or steam applications.

Most failure of gray iron castings in high-temperature service is due to *growth*, which is a permanent increase in volume under repeated heating and cooling. Growth is considered to be caused by the decomposition of the combined carbon content of the gray iron to graphite and to progressive oxidation along the graphite flakes. Irons lower in carbon and silicon are generally less susceptible to growth. Small additions of carbide stabilizing alloys such as chromium, molybdenum, and vanadium reduce growth tendency as does any alloy which increases the density of the metal. The highly alloyed austenitic irons have significantly greater heat resistance than plain or low-alloy irons as well as superior corrosion resistance.

OTHER PHYSICAL PROPERTIES OF CAST IRON. **Electrical Resistivity.** Cast irons vary widely in resistivity, depending on composition. Usual grades of gray irons will have specific electrical resistance of the order of 100 microhm cm but may vary from about 50 to 200 microhm cm. Increasing silicon and carbon both increase resistivity. Because of its rather high specific resistance and ability to be cast in thin and intricate sections, cast iron is used extensively in resistance grids.

Magnetic Properties. Cast iron has poorer permeability and less ability to carry high flux density than rolled mild steel and is no longer used extensively in magnetic applications. Austenitic cast irons high in nickel are of advantage where nonmagnetic properties are desired.

Thermal Conductivity. Thermal conductivity of most cast irons varies from about 0.100 to 0.140 cal per sq cm per sec per cm per °C. Although the heat conductivity is lower than mild steel, cast iron finds some application in heat exchangers, radiators, stoves, etc.

Coefficient of Thermal Expansion. The figure of 0.00001 per °C is most commonly used for cast iron. Table 2 gives data on linear contraction and shrinkage of ten different cast irons.

Solid Contraction. The commonly used figure for patternmakers' shrinkage is $^1/_8$ in. per ft for gray iron and $^1/_4$ in. per ft for white iron.

Melting and Freezing Ranges. The melting and freezing range of cast irons depends largely on carbon equivalent, % C plus 0.3 (% Si + % P); as carbon equivalent approaches 4.30%, the solidification temperature is at the minimum. Most gray irons become completely molten on heating at 2100 to 2400 F. (See liquidus temperatures, Table 2.) On freezing the solidus temperature of unalloyed cast irons is always close to 2100 F.

Specific gravity varies from about 7.00 for a coarse-grained gray iron to about 7.7 for a white iron. Commonly used density figures for gray iron are 0.26 lb per cu in. or 450 lb per cu ft. Densities at several important temperatures in grams per cubic centimeter are given in Table 2.

PRODUCTION. Melting. Cast iron may be produced in the cupola, air furnace, or electric furnace. By far the greatest tonnage of cast iron is cupola-melted. The cupola furnace is a cylindrical-shaft-type furnace similar to the blast furnace but smaller and simpler in construction. In operation, air from pressure blowers is forced into the cupola at the tuyères and through a bed of white hot coke to melt and superheat the iron. The metal charges, consisting essentially of graded pig iron and selected scrap, are interspersed with layers of coke to replenish the fuel bed continually, as the metal is melted. Fluxing material, usually limestone, is charged to remove coke ash and other nonmetallics as liquid slag. The cupola is a continuous melting medium. By selection of raw materials and controlled operation most grades of cast iron may be produced most economically by cupola melting.

For details of construction and operation of the cupola furnace the *Handbook of Cupola Operation*, published by the American Foundrymen's Association, is the most complete and authoritative reference.

Molding. Molding consists of making the form into which the molten iron is cast to shape. The most common mold material is sand, in which the refractory element is silica (quartz) grains bonded with clays or other binders. In natural molding sands the silica and clay occur together in nature. Synthetic sands are compounded of a silica sand to which bonding materials are added. Sand molds are used in both the "green" or moist state and the dry state. Most iron castings are produced by green-sand molding where the molding sand is tempered with water for ramming around the pattern and the metal is poured into the moist mold. In dry-sand molding the moist-rammed mold is oven-dried before casting. Sand molds are rammed by hand or by one of several types of molding machines, the method used depending on the type of casting, the number of castings to be produced, and the facilities of the individual foundry. By the sand-casting method an unlimited number of castings may be produced from a single pattern.

Interior surfaces of castings are usually formed by sand cores. Some interior surfaces may be shaped by the pattern itself, the cores being made of green sand. Most cores, however, are made in core boxes using special core-sand mixtures. For baked cores, a drying oil binder (core oil) is usually used. The cores are baked and affixed into the mold after the pattern has been withdrawn. Baked-oil sand "cores" are sometimes used to form exterior as well as interior surfaces of castings.

Casting. The molten metal drawn from the melting furnace in ladles is poured into the molds. The rate of pouring is controlled by the size of the gate opening into the mold cavity. The metal is allowed to freeze and cool in the mold, and then the casting is removed from the sand for cleaning.

Cleaning. In cleaning castings, adhering sand is removed by brushing, tumbling, or abrasive blasting. Gates, risers, and fins are removed and roughnesses on the casting surface smoothed by chipping and by grinding. Inspection of castings is carried on during cleaning and final inspection after all finishing operations.

2. SPECIFICATIONS FOR CAST-IRON CASTINGS

GENERAL CASTINGS. Specification A-48-46 of the American Society for Testing Materials covers general gray iron castings not covered by other more specific specifications and applies to castings where strength is a consideration. Other general cast-iron specifications, such as Federal QQI-652, use the same scheme and identical requirements as ASTM A48-46. The following important details of this specification are given below, and for the complete specification consult the latest edition of *ASTM Standards*.

It is a purpose of the specification to classify irons according to the minimum strengths of tensile test bars as follows:

Class number	20	25	30	35	40	50	60
Minimum tensile strength, psi	20,000	25,000	30,000	35,000	40,000	50,000	60,000

Transverse tests are optional. When specified the breaking loads shown in Table 3 apply.

Table 3. Dimensions and Minimum Breaking Loads for Transverse Tests

As-cast Round Test Bars			Class No.						
Diam., in.	Length, in.	Distance between Supports, in.	20	25	30	35	40	50	60
			Minimum Breaking Load at Center, lb						
0.875	15	12	900	1025	1150	1275	1400	1,675	1,925
1.20	21	18	1800	2000	2200	2400	2600	3,000	3,400
2.00	27	24	6000	6800	7600	8300	9100	10,300	12,500

Test bars are cast separately from the casting. Three standard sizes of bars are available under these specifications. Tension-test specimens are machined from the round bars cast for the transverse test to the dimensions shown in Fig. 3 and Table 4. The manufacturer and the purchaser should agree on the controlling section of the casting. Then the corresponding test bar shall be used, as shown:

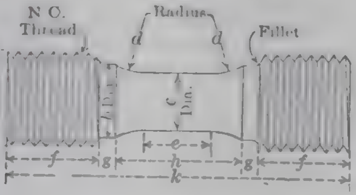

FIG. 3. Standard test specimen. See Table 4.

Table 4. Dimensions of Cast-iron Tensile Test Bars

(See Fig. 3)

Dimensions, in.	Test Bar A	Test Bar B	Test Bar C
a	3/4	1 1/8	1 7/8
b	5/8	15/16	1 7/16
c	0.505	0.750	1.25
d	1.00	1.00	2.00
e *	Shall be equal to or greater than *c* (diameter)		
f	1.00	1.00	1 3/4
g	0.25	0.25	5/16
h, minimum	1.25	1.50	2 1/4
k, minimum	3.75	4.00	6 3/8

* Length of parallel.

Controlling Section of Casting, in.	Test Bar Diameter, in.
0.50 and under	0.875
0.51 to 1.00	1.20
1.01 to 2.00	2.00
Over 2.00	2.00, or by agreement

Test bars should be made under the same sand conditions as the castings and the bars poured from ladles of iron used to pour the castings. If castings are heat treated, the test bars receive the same heat treatment.

Tension-test specimens must be loaded axially, preferably with self-aligning shackles, and at a rate of not over $^1/_8$ in. per min above 15,000-psi stress. The transverse test is made on the bar as cast with central loading between the supports. Corrections are made for sizes of round bars as shown in Table 5. In all bars the controlling dimensions are the diameter of the bar at fracture. The rate of application of load should be such that fracture is produced in not less than 15 sec for the 0.875-in. diameter bar, 20 sec for the 1.20-in. diameter bar, and 40 sec for the 2.00-in. diameter bar.

.900	1.087	0.972	1.25	1.130	0.960	2.05	1.076	0.976
.905	1.106	0.967	1.26	1.158	0.952	2.06	1.092	0.972
.910	1.125	0.962	1.27	1.185	0.945	2.07	1.109	0.967
.915	1.143	0.956	1.28	1.214	0.938	2.08	1.125	0.962
.920	1.162	0.951	1.29	1.242	0.930	2.09	1.141	0.957
.925	1.181	0.946	1.30	1.271	0.923	2.10	1.158	0.952

In case of a failure of a test bar to meet the requirements, a retest may be made. If the retest fails, the castings should be rejected, except that a failed transverse bar may be qualified by a satisfactory tension test on a specimen machined from the broken end of the transverse test bar.

It is the intent of these specifications to subordinate chemical composition to physical properties. The quantities of any chemical elements in the cast iron may be specified by agreement between the manufacturer and the purchaser.

As an aid to selecting the proper composition of gray cast iron, Table 6 gives suggested analyses for various section sizes to meet the strength requirements of ASTM A-48-46. The values set forth in this table are only suggestions and not a part of the specifications, but they have been computed carefully and checked against actual successful practice. The analyses shown presuppose that no alloying elements are to be used.

AUTOMOTIVE CASTINGS. A more specific specification for gray iron castings is ASTM A-159-44T for automotive gray-iron castings. The physical requirements based on the 1.20-in. diameter bar and the standard tests described in A-48-41 are given in Table 7. This specification is identical with the SAE specifications for automotive castings.

An appendix to specification A-159-44T gives uses and typical base compositions of the five grades. This is not a part of the specification and is shown for information only in Table 8.

ALLOY IRON CASTINGS. There are many applications for cast iron where the efficiency or service life of the castings may be materially increased by alloying. Table 9 shows some specific alloy compositions which have been found to be of commercial value. The applications were selected from *The Alloy Cast Iron Handbook*, published in 1944 by the American Foundrymen's Association. For specification purposes the information in Table 9 may be used as a guide to the alloy type and generally expected properties. In purchasing castings it is advisable to specify the fewest possible compositional and mechanical values which will reasonably assure the required properties. Needlessly detailed specifications work a hardship on the foundry and often significantly increase the cost of the castings.

3. FACTORS AFFECTING THE QUALITY OF IRON CASTINGS

METAL STRUCTURE. Suggested compositions for various castings are shown in the preceding article of this section under specifications, and the general effects of the normal elements in iron and steel are given in Section 2. The engineering properties of cast iron are dependent on the degree of graphitization or the relative proportion of carbon in the combined and in the free or graphitic form as well as on the total carbon content.

Carbon and silicon are the principal graphitizing elements and as the amounts of these are increased, with other factors the same, the graphite content of the iron is increased and the metal becomes progressively softer and weaker. As amounts of carbon and silicon are lowered the iron becomes progressively harder and stronger. It seems paradoxical that carbon in gray cast iron is a softener, whereas carbon in steel is always a powerful hardening agent. The explanation is, of course, that as carbon in cast iron is increased the content of soft graphite is increased, and the combined carbon, the hardening agent, is usually decreased. Other elements promoting graphitization are nickel, copper, aluminum, titanium, and zirconium. Elements which retard graphitization include manganese, sulfur, chromium, molybdenum, vanadium, and tellurium.

Other than composition, the prime factor affecting the degree of graphitization in cast iron is the cooling rate during and subsequent to freezing. Slow freezing and cooling allow graphitization to proceed to the maximum extent, and rapid cooling prevents graphitization. For sand castings, section size, by affecting freezing rate, is the principal factor affecting graphitization. To produce uniform properties of metal the composition must be balanced with respect to section size and cooling rate. Table 6 exemplifies the balancing of composition by lowering silicon and carbon to retain the same strength as section size increases. Ladle additions of graphitizing or graphite-retarding alloys are also valuable to control graphitization of iron.

The best combination of strength and toughness in cast iron is obtained when graphitization is so controlled that about 0.50 to 0.90% carbon is retained in the combined form. This content results in a substantially pearlitic matrix. Reduction of the total carbon content while retaining a pearlitic matrix reduces the graphite content and produces a stronger, tougher iron. Maximum softness and machinability in cast iron occur when all the carbon is in the free or graphitic form and when the graphite content is high. Maximum hardness and wear resistance in iron occur with all the carbon in the combined form (white iron).

Besides the proportion of combined and graphitic carbon, another factor affecting the engineering properties of cast iron is the graphite-flake type and distribution. A joint committee of AFA and ASTM has provided a standard method of rating graphite flake size and type. (ASTM A247-41T.) Fine, interdendritic segregates of graphite (Type D) confer ease of machining but impart many undesirable properties, such as poor wear resistance and a low ratio of strength to hardness. The randomly distributed normal graphite flakes (Type A) are usually preferred for engineering irons. A ladle treatment of molten iron known as "inoculation" is very effective in promoting Type A graphite and preventing Type D. Inoculation consists of adding to the molten iron some elements, such as silicon, graphite, titanium, or zirconium, either singly or in combination with other alloys. Addition of an inoculating alloy to the ladle just before casting is much more effective than melting the same alloy through the cupola. The basis of some proprietary cast irons is a standardized inoculation practice for structure control.

HEAT TREATMENT. Although iron castings are not as regularly heat treated as steel castings, many of the properties of as-cast iron may be conveniently varied by several types of heat treatment. The graphite pattern of gray iron, which is formed during freezing, is not significantly changed by heat treatment, but the matrix properties are affected as they are in the heat treatment of steel. Annealing consists of heating the iron casting to above the transformation range, which is usually at 1300 to 1350 F, and cooling slowly. This decomposes some of the combined carbon content to graphite, relieves stresses, and softens the castings. Annealing is used advantageously to increase the ease of machining, particularly for production-machined small castings in the automotive and household appliance industries.

Hardening of iron castings is accomplished by the same methods used in hardening steel, i.e., by heating to above the transformation temperature and quenching, usually in oil. Cast-iron engine-cylinder liners are often oil hardened to produce an effective wear-resistant material with a martensitic matrix but with graphite flakes to prevent galling and to act as oil reservoirs. Iron castings are also flame hardened to increase the hardness at wearing surfaces.

Stress-relief heat treatment consists of heating castings to a subcritical temperature, about 1100 to 1300 F. This treatment increases dimensional stability and is used for castings that are subsequently to be machined to close dimensional tolerances.

WELDING. The welding of iron and steel is discussed in Section 21. The most-used methods of welding cast iron are: (1) fusion welding, with oxygen and acetylene; (2) brazing or bronze welding; and (3) arc welding with a high nickel rod. Most newer specifications permit welding of iron castings to repair minor defects. With proper precautions in preheating and stress relieving such welds are entirely satisfactory.

INSPECTION. Castings inspection depends so much on the service required of the part that it is difficult to generalize. Where possible, the degree and kind of inspection required should be written into the specification or order. The material specifications given in Article 2 of this section are useful in designating the type of iron and the strength properties required. For specific services special inspection is often required. Castings subject to pressure should always be tested prior to shipment at a higher pressure than that expected in service. Castings subject to gas pressure must always be tested with gas or air, not with hydraulic pressure.

Soundness in critical areas may be insured by specifying radiographic inspection. Freedom from cracks and hot tears is best guaranteed by specifying magnetic particle inspection of critical areas. There is an increasing trend, for critical services, to specify mechanical proof testing of castings under some sort of simulated service conditions.

4. STEEL CASTINGS

DEFINITIONS. Steel is an alloy, primarily of iron and carbon, which is usefully malleable as cast. Steel is differentiated from cast iron not only by its malleability but also by the fact that steel contains neither carbide eutectic nor graphite eutectic in its structure. Steel castings are steel parts which are cast in molds to shape so that no further mechanical working is required.

TYPES. There are five classes of commercial steel castings: (1) low-carbon steels (carbon content below 0.20%); (2) medium-carbon steels (carbon content 0.20 to 0.50%); (3) high-carbon steels (carbon content above 0.50%); (4) low-alloy steels (alloy content below 8%); and (5) high-alloy steels (alloy content above 8%).

The medium-carbon steel class represents the bulk of steel-castings output and is considered the "regular grade" product. The high- and low-carbon grades are special carbon steels made to develop the special qualities imparted by high- and low-carbon contents. The distinction between carbon steels and low-alloy steel is necessarily vague, as accurate definitions of alloy steels have not been formulated. In general, if a steel casting contains intentionally added alloy in more than the following percentages it will be considered an alloyed steel casting: manganese, 1.00; silicon, 0.70; nickel, 0.50; copper, 0.50; chromium, 0.25; molybdenum, 0.10; vanadium, 0.05; tungsten, 0.05; aluminum, 0.10; titanium, 0.05; zirconium, 0.05; sulfur, 0.06; and phosphorus, 0.05.

In the low-alloy steels the elements manganese, chromium, molybdenum, and nickel are usually added either singly or in combination for the purpose of increasing hardenability. High-alloy steels, which may be considered to be those containing more than 8% of total alloys, range from the simpler heat- and stain-resisting steels up to the "alloy castings," which contain so little iron that they may be considered not steels at all.

USES. Steel in the cast form is not essentially different in engineering properties from rolled or forged steel, and in general any steel part which may be economically formed by the casting method may be specified as a steel casting. Modern use of steel castings for such critical parts as engine crankshafts, aircraft radial-engine cylinder barrels, and highly stressed gears has largely dispelled the old idea that cast steel may be unsuitable for the most severe services. As compared to other cast ferrous materials, steel castings have higher strengths, higher ductility, and greater toughness.

The following list shows by industries the more important industrial applications where the use of steel castings is well established.

Automotive Industries. Although gray iron castings predominate in castings for passenger-car parts, in heavy-duty truck, bus, and tractor parts many steel castings are used for their higher strength and dependability. Such parts as spring shackles, engine supports, clutch supports, axle parts, axle housings, side frames, tractor treads, and sprockets are often made of cast steel.

Boiler and Tank Construction. Many of the fittings used with tanks and boilers are cast steel. Cast-steel saddles and nozzles, weld necks, pipe flanges, manifolds, and crossovers are regularly used.

Crushing and Grinding Equipment. Crusher jaws and other abrasion-resisting parts are often made of high (12 to 14%) manganese steel, which develops special resistance to battering types of service. Typical steel castings used in cement mills include riding rings or tires, feed and discharge-end heads, rollers, liners, and plates. Many heat- and corrosion-resistant alloy castings are used in these services.

Electrical Machinery. Armature parts, commutator rings, couplings, stator and rotor parts, motor frames, and housings are some of the more common types of steel castings used by the makers of electrical machinery.

Engine Castings. For many types of power units, reciprocating, air, gas, and diesel, steel castings are used for such parts as cylinders and cylinder heads, gears, flywheels, crankshafts, pistons, connecting rods, manifolds, frames, and housings.

Machine Tool Industry. For such tools as lathes, boring mills, planers, milling machines, and grinders, steel castings are used for cams, chuck bodies, clutches, levers, gears, bases, sprockets, wheels, and worms.

Oil Fields and Refineries. For the oil industry many heavy machinery castings and pressure castings are made of steel. Elevated temperature problems in refinery services require many alloy steel castings for strength at high temperatures.

Railways. Railroads were the first large users of steel castings. In locomotives, cast-steel underframes weighing 20 to 50 tons are used. Driving wheels have cast-steel centers. Couplings are often steel castings. Freight and passenger car underframes may be made of one-piece steel castings. Railroad-car truck bolsters and side frames are of one-piece cast-steel construction, including the journal boxes. About 35% of the weight of the modern locomotive and 16% of the modern freight car are cast steel.

Rolling Mills and Steel Plants. Rolling-equipment parts that are subject to high stresses are usually cast steel. The mill roll housings, pinions, couplings, etc., are steel castings. The rolls themselves are sometimes steel castings. Table rollers and guides are often made of cast alloy steels. In furnace equipment the charging boxes, annealing boxes, and ingot car bodies are steel castings.

Ship and Marine Castings. On ships the stem is a steel casting, the rudder posts and frames, hawse pipes, davits, winches, struts, and other castings are usually steel. Propul-

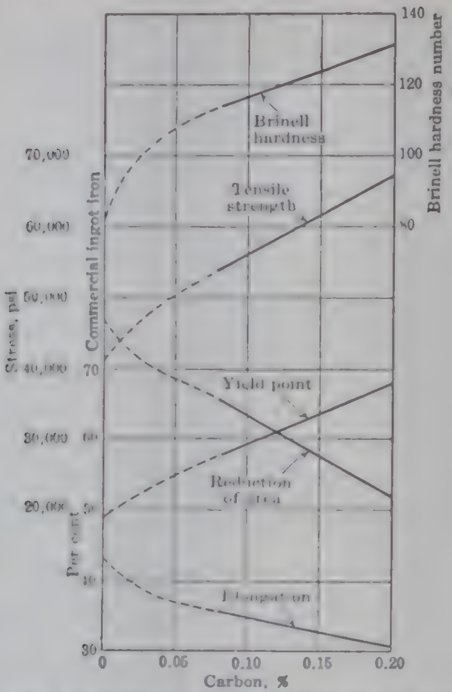

Fig. 4. Mechanical properties of full-annealed low-carbon cast steel. (Reproduced by permission from *Steel Castings Handbook*, Steel Founders Society of America)

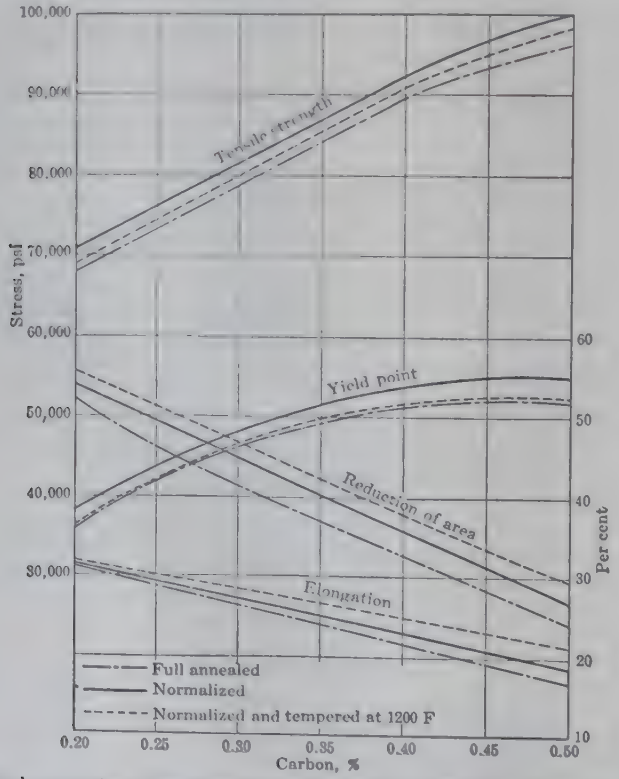

Fig. 5. Mechanical properties of heat-treated medium-carbon cast steel. (Reproduced by permission from *Steel Castings Handbook*)

sion shafting has been made of centrifugally cast steel tube sections welded together. Many cast-steel valves and pressure fittings are used in marine construction.

Many other industries such as paper, rubber, sugar, and textile use cast-steel parts.

PROPERTIES. The mechanical properties and physical constants of steel in the cast state are not essentially different from those of steel in the rolled or forged form. In the ordinary tension test for steel products cast steel will show lower values of elongation and reduction of area than comparable rolled steel tested in the direction of rolling. Rolled steel tested transversely, however, may show lower ductility than cast steel which, when properly heat-treated, does not show directional properties.

The average tensile values to be expected for cast carbon steels are very conveniently given by Figs. 4, 5, and 6, from the *Steel Castings Handbook*, published by the Steel Founders Society of America. The properties shown result from representative testing of standard round tensile bars machined from cast coupon bars. These are expected values and are not to be used as minimum specification values.

Quenched and tempered carbon steels and alloy steels normalized or quenched and tempered of course show much higher strength and higher ductility at a given strength level. The values of Fig. 7, also taken from the *Steel Castings Handbook*, show typical tensile values obtainable from a low-alloy cast steel quenched and tempered.

Where cast-steel parts are subject to fatigue stresses, an endurance ratio of 0.40 to 0.50 (endurance limit to tensile strength) is usual for cast steels. A recent study by C. E. Sims, reported in *The Foundry*, May 1945, showed that there was little difference in the endurance limits obtained on bars cut from forged and from centrifugally cast engine cylinder barrels.

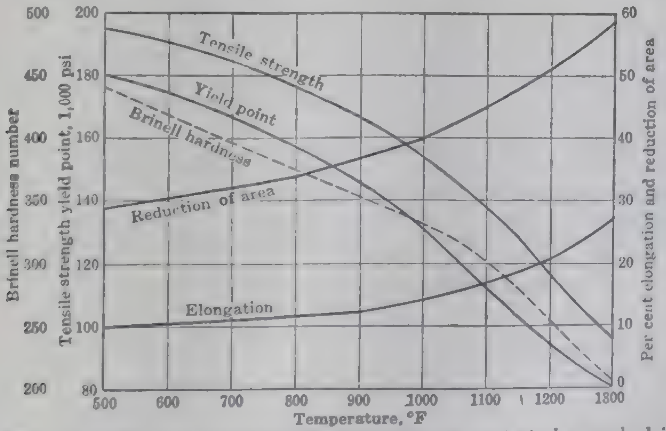

FIG. 7. Mechanical properties of nickel-chromium-molybdenum cast steel quenched in water from 1545 F and tempered at indicated temperatures. (Reproduced by permission from *Steel Castings Handbook*)

PRODUCTION. Melting. The various types of melting equipment used for the production of wrought steel products are all adaptable for producing castings. The available processes are: open-hearth (acid and basic), electric arc (acid and basic), converter, electric induction, and crucible.

Although the equipment is the same as for wrought steel, the processes may be different, since only thoroughly "killed" or deoxidized steel is suitable for castings (see Section 2, Article 2. Good-quality steel for castings may be produced by any of the foregoing types of melting, although the crucible process is rarely used. The basic processes allow reduction of sulfur and phosphorus during the steel melting, but in the acid processes control of these elements is obtained only by selection of the raw materials. In foundries where large tonnages of steel are cast the open-hearth processes are most favored. Smaller jobbing foundries usually prefer the flexibility offered by the electric-arc furnaces.

Molding. Molding practice for steel differs from that for cast iron in several important respects. Because of the higher pouring temperatures required for steel, sands of greater refractoriness are necessary. Silica sands bonded with refractory clays are the essential components of steel molding sand. In order to reduce cost, new "facing" sand is often employed where contact is made with molten steel, and used "backing up" sand of a lower grade in other parts of the mold. No carbonaceous mold materials or washes may be used in steel foundry molding because of the tendency of the metal to dissolve carbon. In another important respect steel molding differs from gray iron molding in that all steel castings must be fed in the heavy sections if castings free from shrinkage are to be produced.

Cleaning and Finishing. Feedheads and gates on rough castings are removed by torch burning, sledging, shearing, or sawing. Torch burning followed by grinding is most used. Most steel castings are heat treated, after which the casting surfaces are cleaned by abrasive or shot blasting.

5. SPECIFICATIONS FOR STEEL CASTINGS

In drawing up specifications for steel castings to insure the desired quality there are two broad considerations: (1) the quality of the metal from which the castings are made and (2) the quality of the castings themselves. The quality of the metal is controlled by specifying chemistry, heat treatment, and physical and mechanical test values on specially cast coupon bars in which the metal is perfectly sound and in the best possible cast condition. It is sometimes argued that the physical properties of the coupon bar have little relation to the properties of metal in the actual testing. However, the coupon bar tests are properly considered to be nothing more than tests of the quality of metal as melted and cast in the best possible form. As such, these tests actually prove steel quality and melting practice and do not guarantee casting quality. The quality of castings themselves is controlled by visual inspection, by specification of some type of soundness test, or by other requirements to insure that the casting will have the desired qualifications. Metal quality is more easily generalized in the standard specifications than the actual casting quality, which often must be controlled by specific requirements for each particular type of casting.

ASTM SPECIFICATIONS. The material specifications for nearly all classes of steel castings are well covered by the ASTM. Most of these general specifications require some chemical limits, broad requirements as to heat treatment, and tensile tests on the standard ½-in. diameter, 2-in. gage length tensile bar. Tensile bars are machined from coupons cast either separately or attached to the casting.

Specification A-27 was completely revised in 1946 and issued as A-27-46T Carbon Steel Castings, Mild to Medium Strength, for General Application (Tentative). Table 10 gives the essential chemical and physical test requirements of this specification.

All castings of grades N-2, N-3, 60-30, 65-35, and 70-36 are required to be heat treated. Other grades may be furnished as cast. Provisions are made in this specification for radio-

graphic inspection and magnetic particle inspection of the castings when agreed on by manufacturer and purchaser.

ASTM A-148 specification was also extensively revised in 1946 and reissued as A-148-46T, High Strength Steel Castings for Structural Purposes (Tentative). In this specification the chemistry required to meet the specified physical values is left to the discretion of the individual manufacturer except that sulfur is specified at 0.06% max and phosphorus at 0.05% max. Tensile requirements are given in Table 11.

Table 11. High-strength Steel Castings Requirements
(ASTM A-148-46T)

Grade	Tensile Requirements, min			
	T.S., psi	Y.P., psi	Elong., %	R.A., %
80-40	80,000	40,000	18	30
80-50	80,000	50,000	22	35
90-60	90,000	60,000	20	40
105-85	105,000	85,000	17	35
120-100	120,000	100,000	14	30
150-125	150,000	125,000	9	22
175-145	175,000	145,000	6	12

Heat treatment is required for all grades, but the specific type of heat treatment is left to the judgment of the manufacturer.

Radiographic and magnetic particle inspection of the castings are provided for when agreed on by manufacturer and purchaser.

Other ASTM specifications for more specific types of steel castings are:

A128-33	Austenitic Manganese-steel Castings.
A95-44	Carbon-steel Castings for Valves, Flanges, and Fittings for High-temperature Service.
A157-44	Alloy-steel Castings for Valves, Flanges, and Fittings for High-temperature Service.
A216-44T	Carbon-steel Castings Suitable for Fusion Welding for High-temperature Service (Tentative).
A217-46T	Alloy-steel Castings Suitable for Fusion Welding for High-temperature Service (Tentative).
A221-30	Chromium Alloy-steel Castings.
A198-39	20% Chromium, 9% Nickel Alloy-steel Castings.
A222-39	Chromium-nickel Alloy-steel Castings.
A223-39	Nickel-chromium Alloy-steel Castings.
A296-46T	Corrosion-resistant Iron-chromium and Iron-chromium-nickel Alloy castings for General Application (Tentative).
A297-46T	Heat-resistant Iron-chromium and Iron-chromium-nickel Alloy Castings for General Application (Tentative).

For detailed requirements of these specifications refer to the latest edition of *ASTM Standards*, Part 1-A, Ferrous Metals.

SAE SPECIFICATIONS. A *Recommended Practice* for Automotive Steel Castings has been developed by SAE to control the specific attributes of steel castings used in the automotive and allied services. Requirements cover three groups of steel castings. (1) carbon steel castings specified by chemical composition and tensile properties; (2) high-strength steel castings specified by tensile properties; and (3) high-strength steel castings specified by tensile properties and hardenability requirements.

The essential chemical and tensile requirements for the various grades of automotive steel castings are given in Table 12. The test bar for tensile properties is the standard ½-in. diameter, 2-in. gage length bar machined from a cast coupon as in ASTM specifications.

Hardenability. Since many cast-steel automotive parts are of alloy steel used in the quenched and tempered condition, a method of specifying minimum hardenability for cast steel is provided. Requirements are based on the End-quench Hardenability Test (as described in SAE Recommended Practice, Method of Determining Hardenability, *SAE Handbook* or ASTM A-255), using the standard 1-in. around Jominy specimen. Hardenability is specified by the use of Table 13.

For example, it is desired to have a 1-in. thick casting with 105,000 psi tensile strength and of such hardenability that it will harden to the center of section in a water quench.

Table 12. Essential Chemical and Tensile Requirements of SAE Recommended Practice for Automotive Steel Castings

(Adapted by permission from the *SAE Handbook*, 1949 edition)

Grade	Description	Chemical Analyses					Minimum Tensile Properties				Bhn
		C	Mn	Si	P	S	T.S., psi	Y.P., psi	Elong., %	R.A., %	
0022	For carburizing	0.12 to 0.22	0.50 to 0.90	0.60 max	0.05 max	0.06 max	Not required				
0030	General purpose weldable	0.30 max	0.70* max	0.60 max	0.05 max	0.06 max	65,000	35,000	24	35	131
0050	For surface hardness	0.40 to 0.50	0.50 to 0.90	0.20 to 0.60	0.05 max	0.06 max	85,000 † 100,000 ‡	45,000 † 70,000 ‡	16 † 10 ‡	24 † 15 ‡	170 † 207 ‡
0080	Carbon or alloy cast steel	Not required			0.05 max	0.06 max	80,000	40,000	18	30	163
0090	Alloy cast steel	Not required			0.05 max	0.06 max	90,000	60,000	20	40	187
0105	Alloy cast steel	Not required			0.05 max	0.06 max	105,000	85,000	17	35	217
0120	Alloy cast steel	Not required			0.05 max	0.06 max	120,000	100,000	14	30	248
0150	Alloy cast steel	Not required			0.05 max	0.06 max	150,000	125,000	9	22	311
0175	Alloy cast steel	Not required			0.05 max	0.06 max	175,000	145,000	6	12	363

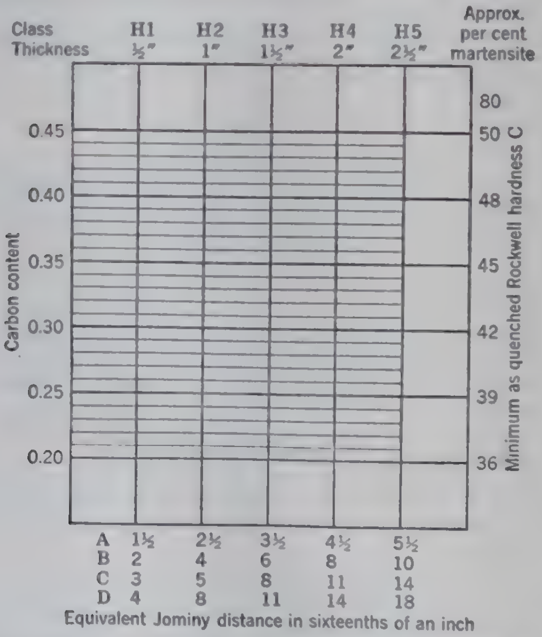
* For each reduction of 0.01% carbon below the maximum specified an increase of 0.04% Mn above the maximum specified will be permitted to a maximum of 1% Mn.

† Normalizing heat treatment.

‡ Quench and temper heat treatment.

Table 13. Critical Section Thickness of Casting

(Reproduced by permission from the *SAE Handbook*, 1949 edition)



A. For desired quench hardness to a depth of one-eighth of critical section thickness—agitated water quench.

B. For desired quench hardness to a depth of one-fourth of critical section thickness—agitated water quench.

C. For desired quench hardness at center of critical section thickness—agitated water quench.

D. For desired quench hardness at center of critical section thickness—agitated oil quench.

One inch thick is class H2. The condition desired corresponds to C, which gives a Jominy distance of 5/16 in. The specification, therefore, would read SAE-0105 H-2C, which indicates to a foundry operating with, say, 0.30% carbon that the material must have sufficient hardenability to produce a minimum hardness of 42 Rockwell C at 5/16 in. from the quenched end of the Jominy bar.

The ASF Recommended Practice for Automotive Steel Castings also provides for radiographic inspection and magnetic particle inspection when so specified in the inquiry and purchase order and when mutually agreed upon by producer and purchaser. For full details of this specification, consult the *SAE Handbook* for 1949 or a later edition.

6. FACTORS AFFECTING THE QUALITY OF STEEL CASTINGS

SOUNDNESS. By modern steel foundry practice it is possible to produce sound steel castings except in the case of an impossible design. Gas porosity, "pinholes," etc., are prevented by proper and thorough deoxidation of the steel and by control of mold conditions. Shrinkage porosity is prevented by adequate feeding and controlled directional solidification. Where an entirely sound steel part is necessary the inspection should be so specified as to guarantee freedom from gas porosity and shrinkage.

There is no reason to tolerate gas porosity in modern steel castings, but some degree of shrinkage porosity is permissible and justifiable economically in many castings. On a plate section of uniform thickness a single riser will feed for only a limited distance, say 12 in. Therefore, to produce a perfectly sound plate casting would require risers spaced not more than 24 in. apart. If a large plate is to be cast, a number of risers must be spaced over the surface, all risers to be cut off and ground in the cleaning process. When such a plate section is insufficiently fed there is shrinkage porosity occurring at the center line of the section. In many cases some center-line shrinkage is not objectionable in the performance of the casting. Parts subject to bending and torsional stresses are little affected by some micro-shrinkage porosity at the center of the section. On the other hand, parts subject to critical tensile stresses should be perfectly sound throughout for greatest efficiency. The cast-steel railroad-truck side frame is an example of a complex plate-section casting which is not perfectly fed, yet withstands the most severe tests and has an excellent record of service. If possible, the user of steel castings should specify the degree of soundness required.

HEAT TREATMENT. Since there is no hot or cold working of the metal in cast parts, grain refinement and structure control are accomplished largely by heat treatment. Most steel castings are improved by some recrystallizing heat treatment, one exception being the very low carbon steels which are relatively unaffected by heat treatment.

Annealing, which consists of heating to well above the critical range and cooling slowly, is the simplest heat treatment as it can be done economically in large batch-type furnaces. Annealing serves the purpose of recrystallizing the metal, refining the grain, and modifying dendritic as-cast structure which has marked directional properties. Annealing usually increases the ductility and toughness of cast steel and promotes a uniform softness throughout the casting.

Normalizing heat treatment consists of air cooling from above the critical range. Normalizing accomplishes the same results as annealing, and the more rapid cooling tends to reduce segregation and promote a more uniform structure. Normalizing may be followed

by tempering at a subcritical temperature to relieve stresses and lower the hardness induced by the more rapid cooling.

Quenching heat treatment effects even more rapid cooling through the critical, with consequently greater uniformity of structure and higher hardness. Quenching is nearly always followed by tempering to stress-relieve and lower the hardness to the desired range. Often, before quenching or normalizing, a preliminary homogenizing heat treatment consisting of a soak at a temperature well above the critical is used. Homogenizing corrects by diffusion the micro segregation of constituents.

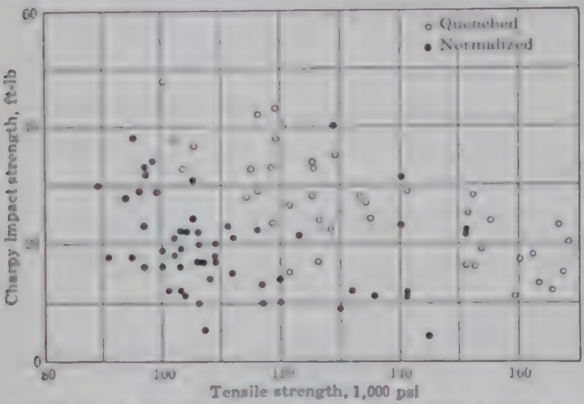

Fig. 8. Effect of heat treatment on Charpy impact strength of 0.30% carbon alloy steels cast in one-inch sections. (Reproduced by permission from paper by Hawkes, *Trans. ASM*, 1947)

Table 14 shows the effect of several heat treatments on the significant properties of a medium carbon steel. The highest ductility and impact values are obtained by quenching followed by tempering at 1200 and 1300 F.

Figure 8 shows how superior impact strength at a given tensile strength level is usually obtained by a quenching rather than a normalizing heat treatment for low-alloy cast steels.

WELDING. The welding of cast steels follows the same principles and methods as the welding of rolled steel of similar composition. All the various welding processes can be used on steel castings, although arc welding and gas welding are the principal processes used in the steel foundries. Resistance, pressure, thermit, and bronze welding are also used in fabricating with steel castings.

Repair welding of steel castings is generally accepted as a satisfactory method of reclaiming castings with minor surface defects. Where practicable, the repair welding should be done before heat treatment, or else the castings should be given a thorough stress-relief heat treatment after welding. The rules to be observed for preheating and stress relieving depend on the steel type and composition and are generally the same as for rolled products. For major repair welds by arc or gas welding the welding rod must be selected so that the weld metal will reasonably match the parent metal in chemistry and hardenability. Rules for welding are given in the ASME Boiler Construction Code and in several ASTM specifications.

INSPECTION. The types and degree of inspection given steel castings depend largely on the intended use. Use of one of the standard material specifications given in Article 5 of this section insures the quality of the metal, but the inspection must further insure the quality of the casting. Visual inspection after cleaning may reveal the surface defects, many of which may be repaired by welding.

Unsoundness due to gas porosity is often evident by visual inspection, as the "pinholes" are usually at or near the surface. Unsoundness due to shrinkage, however, is often deep seated, revealed only by cutting into representative castings or by radiography. Radiographic inspection of metal castings is described by ASTM E-15-39T. Cracks and hot tears are often detectable by visual inspection but are more positively detected and identified by magnetic particle testing. Magnetic particle testing and inspection of commercial steel castings is described in ASTM A-272-44T.

7. DESIGN FOR CASTING

Designers of iron and steel parts to be produced by casting play an important role in controlling the quality and cost of the castings obtained. For most satisfactory results the designer must at all times keep in mind the inherent behavior of molten iron during solidification and the principles of foundry practice. Repetitive castings demand the greatest care in design. The pattern equipment is often complicated and expensive.

Design errors and unnecessary complexities are multiplied in importance by quantity production. Consultation with the foundryman is very often the most effective way for the engineer to produce the design of greatest satisfaction to all concerned.

METALLURGICAL FACTORS, SOLIDIFICATION SHRINKAGE. When a mold is filled with liquid metal, solidification begins by the freezing of a thin shell of metal in contact with the mold. This shell of solid metal grows by thickening inward as heat is conducted away through the mold wall. Obviously, the thinner sections of the casting normally will be completely frozen while the thicker sections remain partially liquid. In the heavier sections, which are the last to freeze, the volume contraction during solidification is manifested by shrinkage cavities unless provision is made to feed in additional liquid metal.

The solidification contraction of medium carbon steel is on the order of 3% by volume, and if steel castings were entirely unfed they could contain up to 3% of shrinkage voids. Since shrinkage will inevitably occur in steel during solidification, the foundryman's only solution to the problem of producing sound castings is to place risers even larger in section over the heaviest sections of the casting so that the riser is the last to freeze and the shrinkage cavity will occur in the riser rather than in the useful casting.

Gray cast iron has a much lower solidification contraction or shrinkage than steel because of graphitization, and for this reason less feeding is required than for steel castings. Many soft gray iron castings of relatively uniform section are cast satisfactorily without any feeding. When the best-quality engineering castings of highest strength gray iron are required, however, the amount of shrinkage approaches that of steel and the steel foundry practice of feeding the incipient shrinkage points must be used.

Solid Contraction. When a casting is completely frozen in the mold, all the shrinkage cavities have been formed and further reduction in volume is due to solid contraction. The linear decrease in size of a casting in cooling to room temperature is compensated for by making the pattern somewhat larger than the desired finished casting. For cast iron this patternmaker's shrinkage allowance is $^1/_{12}$ to $^1/_8$ in. per ft, and for cast steel $^1/_8$ to $^1/_4$ in. per ft, depending on the size and construction of the part.

Solid contraction may cause complications more serious than mere reduction in size. When a part is designed so that it is restricted by the mold or cores from contracting freely, cracking or tearing of the hot casting may occur during cooling. In extreme cases where a long casting is securely held by the mold at both ends, the casting may be pulled in two by solid contraction. Cast steel, with its higher degree of solid contraction, is more susceptible to this effect than gray iron.

The factor of section size influences greatly many properties of the resulting castings. Radical changes in section size in the same casting give rise to localized shrinkage and also increase the dangers of cracking during solid contraction. Thick sections freeze slowly with larger crystals and coarser grain, and will generally have lower strength and ductility than thin-section castings from the same material. On the other hand, large thin-sectioned castings are difficult to run. In gray iron castings there is an additional effect of section size due to the effect of cooling rate on graphitization. An iron which will be soft and gray in a 1-in. section may cast white in a $^1/_4$-in. section. For this reason the effect of section size on hardness and strength is much greater in cast iron than in steel.

PRODUCTION FACTORS. After design, the first step in producing a casting is making the pattern. Single loose patterns require most handwork in molding and leave the gates and risers to be cut by the molder. Gated patterns standardize at least a part of the practice. Metal match-plate patterns are most useful for repetitive production of small castings. Many castings require split cope and drag patterns so that the top half and the bottom half of the mold may be rammed separately. Core boxes for ramming the cores required are also a part of the pattern equipment. Although patternmaking is too large a subject for extensive coverage here, the designer should consider the type of pattern equipment to be used as this may often influence the design to a considerable extent.

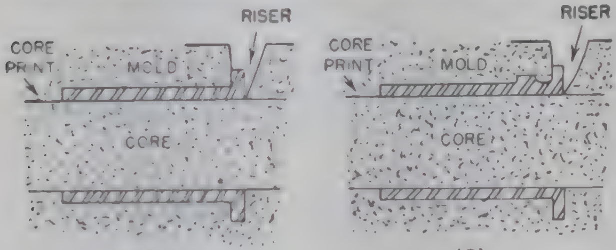
The following specific considerations in connection with pattern equipment should be kept in mind by the designer of cast parts. *Machining allowance* for surfaces to be finished depends on the metal used, the shape of the part, the size, the machining method. In general, $^3/_{32}$ in. to $^1/_4$ in. allowance for cast iron and the same or a somewhat larger allowance for steel castings are sufficient. *Draft* is the taper which must be allowed on all vertical faces of a pattern to permit its withdrawal from the sand. Interior surfaces require more draft than exterior surfaces. The amount of draft normally recommended is never less than one degree. *Core prints*, where internal cores must be used, are necessary to anchor and fix the position of the core in the mold. In general the length of a core print should equal its diameter or width. Often it is necessary for the designer to provide additional openings into an interior cavity to allow adequate core prints.

Parting lines should be made as even as possible to facilitate molding. Often a casting can be redesigned to permit a straight parting line on one plane with consequent saving in cost.

CASTING DIFFICULTIES DUE TO DESIGN. Shrinkage cavities are probably the most commonly encountered type of defect found in castings. The foundryman prevents shrinkage cavities by adequate feeding of the heavy sections, which tend to solidify last.

For casting a part of simple contour and uniform section only one riser may be necessary for a steel casting and none for a casting of soft gray iron where the slight shrinkage occurring will be so uniformly distributed that it becomes inconsequential. Many cast parts, however, must have light and heavy sections. Where light and heavy sections adjoin, risers must be used to feed into the heavy section to produce a sound casting.

Figure 9*A* shows a flanged sleeve casting which is adequately fed with one riser, since freezing will progress directionally from the plain end, and the riser will be the last to freeze. Figure 9*B* shows the same casting with a tapping boss at the top near the flange. To cast this boss sound will require a second riser over the boss. If the boss is run into the flange as shown by the dotted line, however, one riser will still suffice because the isolated heavy section has been eliminated. Avoidance of isolated heavy sections which are difficult to feed simplifies the production of sound castings.



(A) (B)

FIG. 9. Flange casting (*A*), and with tapping boss (*B*).

Hot tears and checks due to solid contraction are particularly amenable to treatment by design revision. Some designs will almost inevitably hot-tear when cast. If the sleeve casting in Fig. 9 had flanges at both ends it would be very susceptible to hot tearing, and the defect would usually appear just back of one of the flanges where the sharp corner of sand creates a "hot spot" which will be weak after the rest of the casting has started to contract. Generous fillet radii at the flanges are the best remedy for hot tearing in this case. Where long straight spokes of a wheel casting tend to pull out because of contraction the trouble has been cured by designing curved spokes which can give without pulling out.

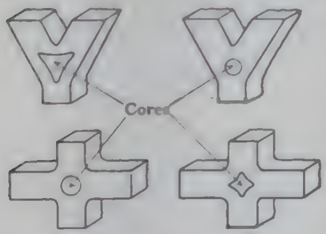


FIG. 10. Methods of insuring equalization of cooling stresses and acceleration of solidification in various types of joined members. (Reproduced by permission from *Cast Metals Handbook*, American Foundrymen's Society, Chicago)

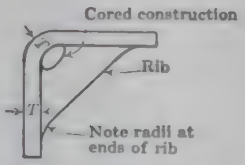

FIG. 11. Cored rib construction. Coring promotes more uniform cooling without impairing the stiffening qualities of the bracket. (Reproduced by permission from *Cast Metals Handbook*)

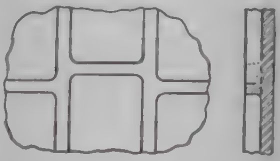

FIG. 12. Avoiding concentration of metal by staggering ribs and webs promotes more uniform cooling and is preferable to the use of cored holes in the center of rib junctions. (Reproduced by permission from *Cast Metals Handbook*)

Mis-runs occur frequently when large thin sections are cast. Core shifts are often due to insufficient openings for prints. Deep recesses and sharp internal angles in cast parts increase the difficulty of cleaning.

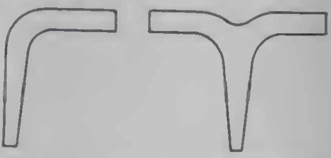

FIG. 13. Methods of joining thick and thin walls. (Reproduced by permission from *Cast Metals Handbook*)

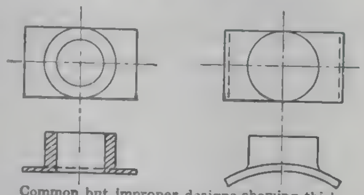
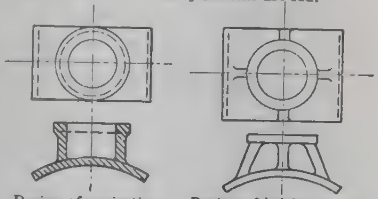
SPECIFIC RECOMMENDATIONS FOR CASTING DESIGN.

1. Try to maintain sections as nearly uniform in thickness as possible (Figs. 10, 11, 12, 13, and 14). Abrupt changes in section are undesirable.
2. Avoid isolated heavy sections. The connecting of adjacent heavy sections simplifies feeding.
3. Indicate fillets at intersections. They should be large enough to prevent hot tearing, but not so large as to cause heavy cross sections which may not be fed through thinner walls.
4. Make castings as simple as possible. When a structure becomes very complicated it is often advisable to cast in two sections instead of one.
5. Use cores as sparingly as possible and keep them simple.

6. Avoid large areas of thin sections, which are difficult to run.
7. Allow sufficient draft to permit easy withdrawal of patterns, and avoid undercuts to permit straight drawing.
8. Design for easy division of the pattern; straight parting lines are most desirable.
9. Indicate allowances for finish-machining on individual surfaces, or note on the drawing.
10. Incorporate in the drawing pertinent information such as pressure tightness, highly stressed sections, and radiographic or magnetic particle inspection.
11. Consult with the foundryman on questionable points or where there is a choice of several possible designs.



Common but improper designs showing thick sections conjoined to a thin main casting section through which the heavy sections are fed.



Design of projection on cylinder cored for equalization of section.

Design of bolting pad on cylinder either cored or welded construction.

8. SPECIAL CASTING METHODS

Most iron and steel castings are produced by the usual static casting methods in sand molds, but some casting methods which require special designs and techniques are also of commercial importance. Among them are (1) precision casting, (2) metal-mold casting, and (3) centrifugal casting.

PRECISION CASTING. The casting process using wax (or other meltable) patterns and poured "investment" molds is called precision casting. The process is fully described in Articles 22, 23, and 24 of this section. Not often used for regular grades of iron and steel, precision casting is of considerable importance for some of the special high-alloy steels and irons. Many of the stainless and heat-resisting steels which are difficult to forge and machine to form intricate small parts are formed to shape economically by precision casting. Very hard steels, like some tool steels, which are practically unmachinable, are best formed to accurate final dimensions by precision-casting methods.

METAL-MOLD CASTING. The principal use of metal-mold or die-casting processes is in the production of lower-melting nonferrous metals, but there are some important uses of these methods in iron and steel casting. The metal-mold material for casting ferrous metals is usually either a soft high-carbon gray iron or a ductile low-carbon alloy steel. Resistance to cracking by thermal shock is the important property for a mold material. Copper molds are sometimes used.

The largest use of a metal mold process in gray iron casting is in the production of metal-mold centrifugal cast-iron pipe. Also, several types of small automotive and household-appliance iron castings are produced by static metal-mold casting (gravity die casting). Where machinable and impact-resistant gray iron castings are required, metal-mold castings usually must be annealed to decompose excess combined carbon formed by the chilling action of the mold. Some steel casting in metal molds is practiced in conjunction with centrifugal casting.

CENTRIFUGAL CASTING. The use of centrifugal force in casting metals may confer several advantages both in economy of production and in quality of product. Several centrifugal casting methods are used in commercial production of iron and steel castings.

True centrifugal casting is used for pipe, tubes, cylinder barrels, and other generally cylindrical parts. The mold is rotated about its own axis, usually in the horizontal plane. Molten metal introduced into the spinning mold is thrown to the mold wall where it is held by centrifugal force until solidified. A perfectly cylindrical interior is thus formed without the use of a center core. Spinning speeds are such as to give a centrifugal force of the order of 50 to 100 times gravity. In addition to the advantage of eliminating center cores, the centrifugal pressure helps to eliminate gas holes and nonmetallic inclusions.

The true centrifugal process finds its largest application in the production of centrifugal cast-iron pipe. Processes using both sand molds and metal molds are in commercial use. The metal-mold pipes are annealed or normalized after casting. Centrifugal cast-iron pipes are cast in 16-, 18-, and 20-ft lengths and in diameters up to 48 in. Steel tubes and cylinders are cast by the true centrifugal process. The process is important for production of tubing in several types of high-alloy compositions which are difficult to pierce and roll into seamless tubing.

Disk- or wheel-shaped parts are centrifugally cast by what is called the semicentrifugal process. The mold is spun about the vertical axis, and metal is introduced into a downgate at the center of the mold. Centrifugal force throws the liquid metal to the periphery, and the pressure aids in feeding the rim sections. Such parts as gears and flywheels in both iron and steel are cast by this method.

Odd-shaped parts not adaptable to the other centrifugal processes are cast by the centrifuge method. Molds are spaced at the periphery of a revolving turntable, and the metal is introduced at the center axis and led into the mold cavities by radial sprues. The increased fluid pressure by reason of centrifugal force aids in filling the mold. Centrifuging is often used in conjunction with precision casting.

MALLEABLE IRON CASTINGS

By James H. Lansing

9. CHARACTERISTICS AND USES OF MALLEABLE IRON

Malleable iron is an alloy of iron and carbon, including smaller amounts of silicon, manganese, phosphorus, and sulfur, which after being cast is converted structurally by heat treatment into a matrix of ferrite containing nodules of temper carbon. The value of malleable iron as an engineering material is in its versatile castability, its ability to withstand and absorb repeated shocks, its ductility, its excellent corrosion resistance, and the remarkable ease and speed with which it can be machined. It was produced originally in Europe following Réaumur's discovery early in the eighteenth century that brittle white cast iron (iron having all its carbon in the combined form), heated to a high temperature for an extended period, will become relatively soft, tough, and ductile. It was known as "white-heart" malleable iron because malleability was acquired more by decarburization (removal of the carbon) than by a permanent conversion of its form.

Since early in the nineteenth century, malleable iron in America, and largely in Europe, too, has been of the "black-heart" type, discovered by Seth Boyden. It attains its properties of toughness and malleability, yet easy machinability, by a complete heat conversion of the carbon from the combined to the free nodular form. Europeans refer to it as black-heart malleable iron, because of its dark fracture, but in the United States it is properly called malleable iron.

Malleable iron castings are produced to physical, rather than to chemical, specifications, because their content of certain elements may be varied, depending on the amount of other elements present. In addition, the quality of the product depends largely on the heat conversion of all its carbon to the free nodular form, called temper carbon.

USES. Applications of malleable iron have progressed as have man's forms of transportation. For safety in transportation, tough and shock-resistant materials are required. Early use included saddlery hardware, then wagon and carriage parts. Agricultural implements, although not strictly forms of transportation, are akin to them and early relied on malleable castings for many of their important parts. Then, and now, plows, cultivators, mowers, reapers, binders, and spreaders incorporate malleables in their construction.

In the development of the railroad industry, malleable castings also found wide use as brake heads and fulcrums, journal boxes and lids, drawbars, brackets, door fasteners, stake pockets, tie plates, rail braces, etc. Today the largest railroad uses of malleables are in brake heads and fulcrums, brake wheels, geared brake parts, and steam and airline connectors.

With the advent of automotive transportation, however, malleable iron entered what has come to be its greatest field of usefulness. Steering-gear housings, differential cases, carriers and bearing caps, hubs, pedals and pedal brackets, motor-truck spring hangers, mountings, rear-axle housings and brake supports all must stand severe service and yet permit high-speed quantity manufacture. Malleables, being castings, can incorporate many required elements in one part and are easily and rapidly machined for their final use. Today 500,000 tons of automotive malleables are required annually.

METALLURGICAL STRUCTURE OF MALLEABLES. Malleable iron castings have a tough but relatively soft and ductile matrix of ferrite, throughout which are scattered nodules of temper carbon. Gray iron, on the other hand, has a ground mass of a hard material, pearlite, and a soft material, ferrite, with graphitic flakes distributed through it. The proportions of ferrite, pearlite, and graphite are largely governed by chemical composition, temperature, and rate of cooling. Hence a gray iron casting with both light and heavy sections may vary considerably in structure due to the difference in cooling rates of the various sections, more ferrite and graphite being present in the heavy sections and more combined carbon in the light.

The average steel casting has a ground mass of free ferrite and pearlite. The amount of pearlite and possible hardness are dependent on the carbon content. Steel castings, however, like malleable castings, have good ductility. Their structure does not vary to any considerable degree in light and heavy sections unless the difference in size is substantial. In such cases grain size may vary considerably. Steel castings are generally used in heavier applications than malleable, have better resistance to abrasive wear, but are not so easily and rapidly machined as malleable castings.

The matrix of malleable iron is ferrite; thus it somewhat resembles wrought iron, with nodules of temper carbon taking the place of the slag particles in wrought iron. Malleable iron has the greater strength due to the higher silicon content of its ferrite. Its uniform structure and fine grain size result from the heat-conversion process which is a part of its method of manufacture. Softness, ductility, and freedom from internal stress are thus assured in malleable iron castings.

10. PRODUCTION OF MALLEABLE IRON CASTINGS

CASTING. The white iron castings from which malleable ones are made are produced in green sand molds from metal melted in an air furnace of the acid-hearth reverberatory type. The metal may originally have been melted in a cupola; but in such case subsequent refinement, in an air or electric furnace, prior to casting, is essential for the proper control of the elements, so that the composition may permit conversion into malleable iron by subsequent heat treatment.

For direct pulverized-coal-fired air furnace melting, the metal charge usually consists of

Pig iron, 25 to 40%; typical amount 33%
* Sprue, 45 to 55%; typical amount 50%
Malleable scrap, 10 to 25%; typical amount 12%
Steel scrap, 0 to 15%; typical amount 5%

* Gates, runners, and any scrap castings from previous heats.

For duplex melting, original cupola melt with subsequent air furnace or electric furnace refinement, the cupola metal charge is usually

Pig iron, 5 to 20%; typical amount 12%
Sprue, 45 to 55%; typical amount 50%
Malleable scrap, 0 to 15%; typical amount 8%
Steel scrap, 15 to 45%; typical amount 30%

The decreased amount of pig iron and increased amount of steel scrap used in the cupola charge prevents the production of a metal too high in carbon content. In direct-air furnace melting more pig iron and less steel scrap may be used, as the metal is not in direct contact with the fuel, as is true in the cupola, and therefore does not absorb as much carbon.

With a proper initial silicon and carbon content of the air-furnace charge, the oxidizing action of the furnace atmosphere lowers the silicon and carbon content of the metal, both during melting and while it is being superheated, to a point where no carbon (primary graphite) will be precipitated on solidification. The castings therefore exhibit a white fracture, and are known as white or "hard iron." Duplex melting shows the same result, except that the original, and continued, charge of the air furnace consists of molten metal. Duplex melting is generally employed in conveyor-equipped plants where a continuous supply of molten metal is required.

COMPOSITION. In respect to factors other than carbon content, malleable castings may be of the same chemical composition regardless of whether medium elongation or high elongation material is being produced. Medium elongation malleable iron is covered by ASTM A-47 grade 32510, and high elongation malleable iron by ASTM A-47 grade 35018. (See Article 11 following.)

For the production of either grade, the silicon content normally ranges from 0.85 to 1.30%, most plants generally averaging slightly over 1.00%. As high silicon decreases the annealing time requirement, some plants produce castings with silicon of 1.30 to 1.80% or even higher. In such cases precautions must be taken to prevent the formation of primary graphite as the castings solidify. The precautions include the use of a largely nongraphitic charge, higher superheat of the metal, accelerated cooling of the castings, and the avoidance of production of heavy sectioned castings. High-silicon malleables, in general, meet the requirements of the 32510 grade ASTM A-47.

Sulfur content ranges from 0.05 to 0.20%, depending on whether direct air furnace melting or duplex melting equipment is employed. The sulfur content of air furnace malleable will normally run from 0.06 to 0.10%, that of duplexed malleable from 0.12 to 0.18%. The manganese content is controlled to take care of the sulfur through the formation of manganese sulfide. Otherwise the sulfur would have a stabilizing effect on the iron carbide retarding the anneal. A manganese content twice that of the sulfur plus approximately 0.15% affords a satisfactory margin of safety. Thus with an average air furnace metal of 0.08% sulfur, a manganese content of 0.30 or 0.32% will be used, whereas, with an average duplexed metal of 0.16% sulfur, a manganese content of 0.46 or 0.48% is desirable.

Phosphorus should not exceed 0.18%, as it tends to reduce the impact values of the material, especially if accompanied by relatively high silicon. In the highest silicon ranges, discussed above, phosphorus content should not exceed 0.12%.

The carbon content of the metal when cast, as earlier indicated, is the most important factor in determining whether the final product will be of the medium-elongation or high-elongation type. Hence foundries operating to the 32510 specification grade normally produce metal with a carbon content of 2.40 to 2.60%. Those producing to the 35018 specification grade normally pour metal within the 2.20 to 2.40% carbon range. Those producing the extremely high silicon material must keep their carbon content in the lower range even though operating to the 32510 grade specification. Otherwise their combined silicon and carbon content would produce castings containing primary graphite even in relatively light sections. Such castings would be distinctly inferior in ultimate strength, yield point, and elongation values, and would not be true malleable iron castings.

MALLEABLE HEAT-CONVERSION PROCESS. The malleable anneal, as indicated, is really a heat-conversion process in which brittle white iron castings of suitable composition are rendered tough, ductile, and easily machinable by a complete metallurgical transformation of the metal structure. In the as-cast product all the carbon must be in the iron-combined form, in the final malleable castings none of the carbon is in the iron-combined form.

The castings may be annealed or "malleablized" in periodic furnaces which are coal, oil, or gas fired or electrically heated, or in continuous ovens similarly fired or heated. A type of periodic oven in wide use consists of a large brick chamber in which some 10 or 20 tons of castings are placed in protecting white iron boxes some 2 ft square by 1½ ft deep which are stacked to a height of some 6 ft. The oven is pulverized coal or oil fired, the flame passing through the oven and out through small flues. The iron boxes, containing either sand or slag as packing material or covered by plates, protect the castings from scaling. When gas-fired radiant tubes or electric-heating elements provide the heat, or if a muffle is used, the protecting pots or boxes are not required. Continuous ovens may be of the car or tray type, the former generally being oil or gas fired and requiring the protective pots. Tray-type continuous ovens, radiant tube or electrically heated, again do not require protective pots, but may employ a gas-produced atmosphere to prevent scaling.

A typical pulverized coal-fired periodic type of oven cycle is:

20 hr to attain 1600 F
40 hr at 1600 F
14 hr cooling to 1375 F
30 hr from 1375 to 1250 F
12 hr cooling to handle

Total 120 hours

In a radiant-tube or electrically heated periodic oven the total cycle may require but 60 hr, as the castings are much more rapidly heated and cooled. Continuous ovens further reduce the annealing time requirement as smaller batches are heated in each oven zone and the temperatures of the various zones are constantly maintained.

The decomposition of the primary "cementite and pearlite" structure of the original castings is accomplished by heating the castings and holding them, for a period, well above the critical temperature between 1330 and 1370 F. First the pearlite is transformed into austenite, the structure consisting of free cementite in a matrix of austenite. The austenite is a solid solution of iron containing varying amounts of cementite, depending on temperature and holding period. Then, aided by increased temperature, part of the cementite is dissolved in the austenite. At these elevated temperatures, 1550 to 1700 F, the austenite will dissolve more carbon as cementite than as graphite. Hence, as the castings are held longer at the high temperatures, some of the carbon which was in the cementite separates out of the solid solution in the form of temper carbon. The austenite, no longer saturated with cementite, then dissolves more cementite. The dissolving of the cementite and the precipitation of carbon by the austenite thus proceed simultaneously until all the free cementite has been dissolved and most of the carbon precipitated.

The temperature is then dropped to slightly below the 1370 to 1330 F critical range, and the castings are held there in the 1330 to 1290 F range for a sufficient number of hours to accomplish the breaking down of the austenite into temper carbon and ferrite. Some pearlite is formed at the lower temperatures, but with adequate holding time the cementite of the pearlite is spheroidized and decomposed into ferrite and temper carbon.

11. PROPERTIES AND DESIGN

By malleable casting use it is often possible to conserve metal, machine tools, and man hours. From a strength standpoint, advantage may be taken of the fact that in malleable iron the ratio of yield point to ultimate strength, 65%, is considerably higher than that of many materials of comparable elongation. Also, the notch fatigue ratio of malleable iron is high, this characteristic being further supported by its uniform rather than "directional" strength. Physical and mechanical properties are listed in Table 1.

In the design of parts to be made of malleable iron, its high fluidity and uniform strength and toughness make it possible to place metal in the exact section thickness in the exact locations desired. Interiors may be cored and many desired, or required, features incorporated in one casting with but little subsequent machining.

Table 1. Physical and Mechanical Properties of Malleable Iron

	Standard Grades 32510 and 35018
Shear strength, psi	48,000
Yield strength in shear, psi	23,000
Modulus of rigidity, million psi	10.6
Poisson's ratio	0.17
Brinell hardness number	110 to 135
Endurance limit, psi	31,600
Notch-fatigue strength, psi	About one-third ultimate tensile strength
Modulus of rupture in torsion, psi	58,000
Yield strength (torsion), psi	24,800
Angle of twist at rupture	
Round 0.9 in. diam. 5-in. long	360°
Round 1.0 in. diam. 10 in. long	790°
Charpy (keyhole and V notch) ft-lb	6.5 to 8
Izod (V notch), ft-lb	16.5
Specific gravity, average	7.32
Weight (average), lb per cu in.	0.264
Shrinkage allowance, in. per ft	$1/8$ to $3/16$
Coefficient of thermal expansion, per °F	0.0000066
Specific heat, cal per gram per °C	0.122
Resistivity, microhms per cc	32
Coercive force, amp turns per cm	1.16 to 1.55

MACHINABILITY. It has often been stated that malleable iron is the most easily machinable and free cutting of ferrous metals of comparable or higher strength. The fact that this is so, in a metal that is both tough and possesses versatile castability, accounts for the large use of malleables in the high-speed production automotive industry.

Its high machinability is due to its uniformity of structure throughout and its nodular temper carbon which serves as a substantial lubricant on the cutting point of the tool. The formation of the chips, which generally break up without creating undue pressure on the top face of the tool, avoids the generation of high heat, with a resultant lengthening of tool life.

Illustrative of the machining properties of malleable iron is a table of relative machinability values developed by a producer of machine tools and published in *American Malleable Iron—a Handbook*. This table assigns relative machinability values to a group of the more readily machined steels and to malleable iron, with SAE 1112 steel being rated as the base value of 100. The comparison is shown in Table 2, which is abstracted from the aforementioned table.

SPECIFICATIONS FOR MALLEABLE CASTINGS. The most widely recognized standards for malleable iron castings are those of the American Society for Testing

Table 2. Relative Machinability Values

(Data from *American Malleable Iron—a Handbook*, Malleable Founders' Society, Cleveland, 1944, by permission)

		Machinability Value	Brinell Hardness Number
Standard malleable iron		120	110–145
Pearlitic malleable iron		90	180–200
Pearlitic malleable iron		80	200–240
Steels			
SAE number	AISI number		
1112	B1112	100	179–229
1113	B1113	135	179–229
1120	......	80	143–179
1118	C1118	80	143–179
1137	C1137	70	187–229
1022	C1022	70	159–192
4130	A4130	65	187–229

Materials. Specification A-47 of the ASTM provides for two grades of malleable iron castings with minimum tensile properties as follows:

	Grade 32510	Grade 35018
Tensile strength, min, psi	50,000	53,000
Yield point, min, psi	32,500	35,000
Elongation in 2 in. min, %	10	18

IMPACT RESISTANCE. Competent metallurgists disagree as to the existence of authoritative impact tests for various materials. It is believed, however, that an indication of the toughness and shock resistance of malleable iron is afforded by a wedge test that many producers employ as a shop control of their product.

The wedge and apparatus for making this test are shown in Fig. 1. The wedge is 1 in. wide, and tapers from $\frac{1}{2}$-in. to $\frac{1}{16}$-in. thickness in a distance of 7 in. It is placed on the anvil of the wedge-test machine, and a weight of 21 lb is allowed to fall on the tip of the wedge from a distance of 3.33 ft between the bottom of the tup and the tip of the wedge. Blows of 70 ft-lb are thus struck on the specimen which is tested as cast. It is an extremely severe test, in that the first blow falls on one-sixteenth of a square inch, and each succeeding blow on a somewhat larger section, depending on the extent of the curl of the wedge resulting from the impact of the tup. Wedges tested in this manner regularly run in excess of twenty blows and provide an excellent illustration of toughness and impact resistance.

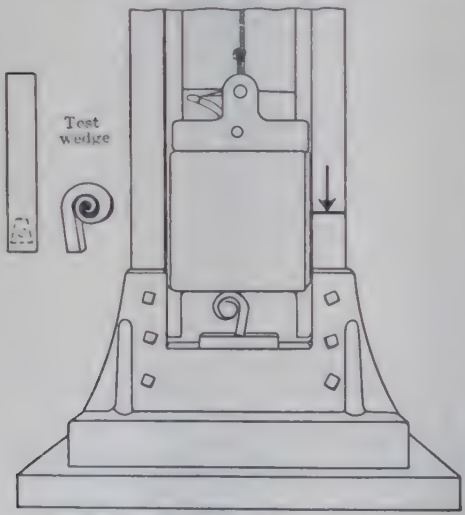

Fig. 1. Wedge test for malleable iron.

CORROSION RESISTANCE. In agricultural implement manufacture, mower and reaper knife guards and shoes, draft brackets, housings, binder needles, yokes, chain, and other castings are of malleable iron. This widespread use in machines which are exposed to the weather, in many cases at all times, attests to the excellent corrosion resistance of the material and further contributes to its large use in tractor, bulldozer, and similar farm, road, and construction machinery. Relatively unprotected railroad use is in malleable brake heads and fulcrums, box-car door hangers, hand-brake wheels and housings, tank-car dome rings and fittings.

In the electrical transmission field, an outstanding malleable application is the insulator caps used in high-voltage lines. Here also, the basic corrosion resistance of malleable iron and the facility with which it takes an excellent hot-dip galvanizing coating, influences its specification for this application.

Unprotected malleable iron castings show excellent corrosion resistance because of the formation of an adherent coating on exposure to the elements. F. L. Wolf and L. A. Meisse (*ASTM and AFA Symposium*, 1931) give the results of a corrosion test of various materials suspended in the smokejacks of a roundhouse which was in continuous use. A six-year comparison established the fact that one month's exposure in the smokejack is equivalent to two years in service. For flat specimens of standard malleable iron the loss by corrosion was only 64% of that shown by similar pieces of basic open-earth steel. Corresponding figures were 51% for malleable iron with 1% copper, and 89% for wrought iron. Round specimens exhibited similar though somewhat less pronounced differences.

SIZE OF CASTINGS. Malleable iron is cast in sections $^1/_{16}$ to 2 in. or more thick. The 2-in. section can be malleablized as completely as the $^1/_{16}$-in. section. Generally, a metal thickness of $^3/_{16}$ or $^1/_4$ in. with strengthening ribs is well adapted for small castings. For castings of medium size, sections of $^1/_2$ to $^3/_4$ in. are typical. Within reason, light and heavy sections may be incorporated in the same castings. For example, an automotive differential carrier, weighing some 20 lb, may have bearing seat sections which incorporate a 1 $^1/_4$-in. cube of metal, but some of its wall sections and ribs may be not over $^1/_4$ in. thick. Approximately 75% of malleable castings produced do not exceed 18 in. in length or 25 lb in weight. Large quantities produced weigh less than 1 lb, and this statement applies also to 5 and 10 lb classifications. Illustrative of what is considered a heavy malleable iron casting is a 300-lb automotive truck rear-axle housing. Such a casting generally has sections varying from $^1/_2$ to 2 $^1/_2$ in. thick, depending on the functions of its various parts.

UNIFORMITY OF STRENGTH AND ELONGATION. The uniform structure of malleable iron and the fact that its strength and elongation are remarkably constant, irrespective of whether the castings are machined or not, is illustrated by a test of as-cast and machined bars.

Bars of $^5/_8$-in., $^3/_4$-in., and $^7/_8$-in. diameter were cast from twenty-seven consecutive heats in one foundry. After anneal, the $^5/_8$-in. bars were tested in the as-cast condition. The bars of larger diameter were machined to the standard $^5/_8$-in. test-specimen diameter before being tested. Ultimate strengths of the as-cast and machined bars were, respectively, 54,800, 53,460, and 53,530 psi. Yield points were 36,500, 35,950, and 36,100 psi, and elongations in 2 in. were 23.4, 22.0, and 20.5%.

12. PEARLITIC AND ALLOY MALLEABLE IRON

PEARLITIC MALLEABLES. Modifications of normal malleable iron, known as pearlitic malleables, have been produced for the past few years when wearing properties, accompanied by a reasonable amount of toughness, are in demand. The product has a matrix which consists of silico-ferrite and pearlite and may contain some spheroidized cementite. The mechanical properties depend largely on the character of the matrix. Briefly, the ultimate strength varies between 60,000 and 90,000 psi, the elongation in the former averaging around 12% and in the latter not more than 3%. The type of material to be specified within the ranges indicated depends on the use to which the material is to be applied.

In general, pearlitic malleable has higher average yield point and ultimate strength, and lower elongation than normal malleable iron. It machines less readily and has a higher indentation hardness. When compared with drop forgings and steel-bar stock of identical Brinell hardness, pearlitic malleable may be machined in less time, with greater tool life, and at less cost. In comparison with forgings it also possesses the general advantages inherent in a cast part. A minimum of draft is needed, interiors may be cored out as required, machine operations are reduced, and much metal is saved. Applications include use where rigidity and wear resistance are important factors, as in gears, sprockets, air tools, and wearing pads.

The ASTM Specification for Pearlitic Malleable Iron Castings, A220-Tentative, provides for four grades conforming to the following minimum requirements for tensile properties:

	Grade 43010	Grade 48005	Grade 60003	Grade 70002
Tensile strength, min, psi	60,000	70,000	80,000	90,000
Yield point or yield strength, min, psi	43,000	48,000	60,000	70,000
Elongation in 2 in., min, %	10	5	3	2
Typical Brinell hardness number range	163-207	179-228	179-241	241-285

ALLOY MALLEABLE IRON. Some malleable iron producers also are engaged in the manufacture of the conventional type of malleable iron to which they usually add a small amount of copper and molybdenum. These alloy castings have found many applications, since they have a yield point of 40,000 to 45,000 psi and an ultimate strength of 58,000 to 65,000 psi, accompanied by an elongation of 15 to 20%.

COPPER-BASE ALLOY CASTING

By H. M. St. John

This chapter is concerned with the casting of alloys in which copper is present as 50% or more of the composition. The engineer who is planning the use of such alloys must deal with the following considerations.

1. *Selection of Alloy.* What alloy will best meet the requirements of the job in hand? If a number of alloys seem suitable, which one can be produced at least cost?

2. *Selection of Casting Method.* The method to be used, sand casting, die casting, etc., may be governed by the alloy selected. Which method will be most economical?

3. *Design of Casting.* How should the casting be designed to permit most economical production from the standpoint of foundry and machine shop?

4. *Specifications and Inspection.* To what extent and in what manner should the properties desired in the casting be insured by examination and test?

The mechanical engineer will also be asked more frequently than in the past to assist in planning foundry layout and in the choice of foundry equipment. These aspects will be discussed separately at the end of this chapter.

13. SELECTION OF ALLOY

Hundreds of copper-base alloys are in common use, but in many instances the differences among them are not significant. On p. 4-26 is a simplified list which includes all the useful alloy types with their properties and the uses for which they are suitable. For our present purpose they may be grouped as follows: (1) Red brasses and tin bronzes. (2) High-zinc alloys, including manganese bronze. (3) High-lead alloys, containing little or no zinc. (4) Aluminum bronzes. (5) Nickel bronzes. (6) Silicon bronzes. (7) Pure copper and alloys consisting of copper combined with minute percentages of hardening elements.

Of these, items 3 and 7 are used only when nothing else will serve, with no question of choice or comparison involved. The aluminum, nickel, and silicon bronzes are usually selected for special properties, particularly their corrosion resistance. The high-zinc alloys are chosen for high strength and rigidity or, sometimes, for low per-pound cost. They are also best suited for forging or permanent-mold casting. The red brasses and bronzes lend themselves best to the sand casting of intricate shapes, with a desirable combination of moderately good physical properties, good bearing properties, and excellent resistance to ordinary corrosion. They are also more readily machinable than most other alloys. The tin bronzes are the usual choice for pressure castings to be used at moderate pressures and at temperatures ranging from subzero to about 500 F.

If sand casting is to be the chosen method and either a red brass or a yellow brass seems suitable, so far as the properties of the product are concerned, red brass or bronze will usually prove to be cheaper, despite the higher per-pound cost, unless the part to be cast is of very simple design or is to be used for structural purposes only, with little or no machining. The use of the high-zinc yellow alloys imposes upon the foundryman a number of problems which substantially increase his processing costs.

14. SELECTION OF CASTING METHOD

The available casting methods are (1) ordinary sand casting; (2) gravity casting in metal molds; (3) plaster-mold casting; (4) pressure die casting; (5) centrifugal casting.

The design engineer must also consider whether the part in question might perhaps be made more economically from rod stock on a screw machine or by hot forging. The latter method is more nearly comparable to casting since it is capable of producing nonsymmetrical parts which cannot be made by the screw machine.

SAND CASTING. All the alloys listed can be sand cast. Practically speaking, the red brasses and bronzes cannot be processed in any other way because of their shrinkage characteristics, their hot shortness, and the manner of their crystallization during shrinkage. An exception to this might be made in favor of centrifugal casting which, in an early stage of its development, promises eventually to be applicable to nearly all casting requirements. The nickel bronzes and most of the nearly pure copper alloys are also limited to sand casting.

Of all casting methods, sand casting requires the least investment in equipment and is most flexible with respect to changes in the design of the product. It permits the use of intricate cored cavities which can be undercut to any desired degree. Precise dimensions are not attainable, machine operations are essential if close dimensional control is required. If the number of parts to be made is not large or if the individual part weighs more than a few pounds, sand casting is the preferred method, regardless of other considerations.

METAL-MOLD GRAVITY CASTING. This method is not widely used but is of particular advantage in connection with the high-lead alloys. Since lead does not mix with the other constituents of the alloy, it tends to segregate undesirably during solidification. Poured into a metal mold the alloy chills so rapidly that the lead can be trapped in a highly dispersed condition. Molds of artificial graphite are sometimes used in place of metal and are nearly as effective. The casting and mold must be designed so as to impose no strain on the hot-short alloy as it cools. If cores are used they must be oil-sand cores or designed to be mechanically collapsible.

PLASTER-MOLD CASTING. In this process the molten metal is poured into plaster molds which have been formed on a pattern, very much as sand molds are made. The resulting castings are very close to dimension and have a smooth finish. Plaster molding is well adapted for making small castings of intricate shape, such as small gears or hardware, which in this way can be made true to finished shape and dimension but would require costly machine operations if made in sand castings. Oil-sand cores are used if cored cavities are desired.

The economical production of plaster-mold castings requires rather elaborate equipment for preparing the plaster mix and for making and drying the molds, which are poured while still hot from the oven. A portion of the broken mold material is reclaimed and processed for re-use. The process is not well adapted to short runs or to the production of any but small castings. High-zinc alloys are used exclusively.

PRESSURE DIE CASTINGS. This process is suitable for certain of the high-zinc alloys, aluminum bronze, and silicon bronze when a large number of small castings are to be made without change of design. Dies and casting equipment are costly.

In this process molten metal in a viscous condition is forced under high pressure into a steel die, which usually has several cavities connected by channels through which the metal flows almost instantaneously. Because of the speed with which the metal fills the die cavities the die designer must provide adequate vents to permit the rapid escape of air from the cavities, particularly from pockets and corners; otherwise the casting will be porous because of trapped air. The metal must be viscous rather than fluid or the metal also will squirt through the vents, and yet this very viscosity makes the trapping of air more likely. Consequently, only light sections of the casting are likely to be perfectly sound. Brass die castings having relatively heavy sections (more than $^1/_4$ in. thick, for example) will commonly be acceptable if they are used for structural purposes only, but are likely to give trouble if there is any machining to be done in the heavy sections.

The refractory alloy steels used for dies have low heat conductivity and are subject to "heat checking" after a few thousand shots, with the result that there is a network of tiny fins on the surface of the casting. If this condition is objectionable from the standpoint of appearance, the casting must be polished or the die must be redressed frequently. This difficulty is less pronounced with the aluminum and silicon bronzes.

There is also a successful patented method for casting aluminum bronze by vacuum instead of by pressure. An assembled die held together by clamps or similar means is connected to a vacuum line and dipped into molten metal, which is thus sucked into the die. Here venting is no problem since the air in the die is sucked out as the metal enters. The process is limited to small castings made in substantial volume.

CENTRIFUGAL CASTING. In this process molten metal is poured into the center of a rapidly rotating mold which may be of either metal or sand. The metal is thrown with great force to the periphery of the mold interior surfaces. The method is in use for making symmetrical brass parts such as rings or cylinders and is capable of giving a very dense, sound structure. Work done with iron and steel would seem to indicate that castings of any desired shape and lack of symmetry can be made in this way. (See Centrifugal Castings, Peter Blackwood and John Perkins, *Trans. Am. Foundrymen's Assoc.*, Vol. 52, 1944, p. 273.) There seems no reason why this method could not be applied to any alloy since the hot shortness of the red metals should offer no difficulty if sand molds are used.

15. DESIGN OF CASTINGS

Much difficulty can be avoided and costs can be reduced if the design engineer will consult the foundryman before the final design is adopted. A design unsuited to the casting method to be used may so handicap the foundryman that he cannot produce economically. Although nothing can fully take the place of such consultation it is possible to state a few basic principles for the general guidance of the designer.

Equipment, Shrinkage. First of all, the foundryman should be given a voice in the selection of pattern and core equipment. Added investment in equipment will often pay its way in reduced operating costs. In patternmaking an allowance must be made for shrinkage of the metal as it solidifies and cools. For the copper alloys this allowance varies from ${}^{1}/_{8}$ to ${}^{1}/_{4}$ in. per ft, but, depending on the design of the casting and the pattern, it will sometimes be found that certain parts of the casting show no shrinkage at all while other parts shrink more than expected.

Thickness, Tolerance, Draft. While it is important to make the casting as light as possible since the copper alloys are expensive, it is false economy to design critical parts of the casting so light as to make foundry production difficult and costly. Minimum sections in sand casting are approximately ${}^{1}/_{8}$ in. for the high-zinc alloys and for aluminum and silicon bronzes. The red brasses and bronzes can be poured to a minimum of ${}^{3}/_{32}$ in. In die casting, sections as thin as ${}^{1}/_{16}$ in. are permissible. Machine finishes should be held to a minimum and the foundryman consulted about the tolerance he requires. Sufficient draft must be provided for drawing the pattern or die.

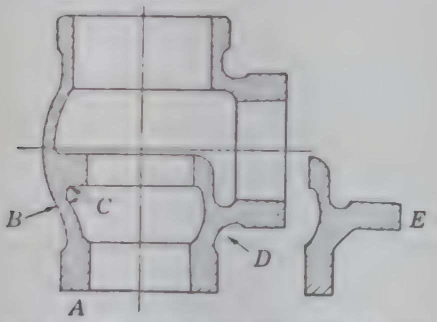

FIG. 1. Addition of rib on detail shown at right permits adequate flow of metal to heavy seat section of casting.

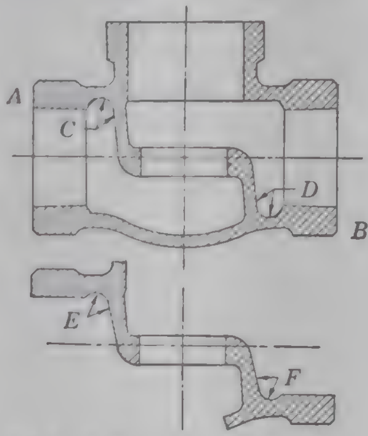

FIG. 2. Redesign shown at E and F improves flow of metal to heavy seat section.

Gating. Abrupt changes from a light to a heavy section are to be avoided, and provision must be made for gating the casting at an effective point. The liberal use of fillets is recommended. Figure 1 illustrates a casting so designed as to make economical production practically impossible. If the casting is gated at A—as good a place as any—the constricted section B will tend to cause a shrinkage cavity at C. By putting a rib across D at the parting line, as shown in the detail at right, the casting can be gated at E and the difficulty disappears. The casting shown in Fig. 2 can be gated at A or B, but the thin section at C and D interferes with proper feeding of the heavy seat section. By changing the design, as shown in the detail at E and F, the trouble is avoided. For a more detailed treatment of this subject refer to the *Cast Metals Handbook*, 1944 edition, American Foundrymen's Society.

Die Casting. In die casting the die cavities are filled almost instantaneously and both castings and gates solidify immediately so that no further feeding is possible. For this reason the whole structure of castings and gates must be designed as if it were a single casting. To this end the die designer must be allowed considerable latitude in determining the design of the casting.

16. SPECIFICATIONS AND INSPECTION

As a general rule the engineer should name the properties he desires in the finished casting without attempting to specify how those properties are to be attained. Visual inspection takes care of matters of appearance; dimensional tolerances can be gaged; castings designed to withstand fluid pressure can be tested for leakage. But the strength of a casting can be determined only by a destructive test. To this end specifications provide for test bars to be cast from each heat of metal as desired and for the destructive testing of these test bars as a measure of the properties to be expected from castings made from the same heat. However, it is of the greatest importance to remember that the properties of the test bar are merely a measure of the quality of the molten metal in the ladle, ready for pouring into castings. The physical properties of the casting itself are further influenced by its correctness of design, the temperature at which it is poured, and by a number of other factors that have nothing to do with the test bar. Standard test bars are castings which have been designed in such a way as to develop maximum physical properties, somewhat higher properties than can be expected in all parts of castings designed for use. Test coupons attached to the casting are not recommended.

DEFECTS. The principal defects in castings, from an engineering standpoint, are shrinkage, blow holes, sand holes, and oxide inclusions. Shrinkage holes are usually found at a point where the heavy and light sections join. Blow holes are due to a faulty molding and melting condition, and sand holes are caused by imperfect molding. Oxide inclusions may be caused by bad material but also, in some alloys, by excessive agitation during the pouring operation either inside or outside the mold.

SPECIFICATIONS. For most applications standard specifications and methods of test have been set up by the American Society for Testing Materials; they are generally accepted and in common use.

17. FOUNDRY LAYOUT AND EQUIPMENT

Modern foundries are rapidly being mechanized and are thus increasingly in need of skilled engineering. This trend results in part from a need for better working conditions since the cheap labor formerly employed in the more laborious and disagreeable phases of foundry work is no longer available. And, since labor is no longer cheap, labor-saving equipment is greatly in demand.

Formerly molders were craftsmen who used their skill and experience in the making of molds, then poured and shook them out. Now the molder is a machine operator who does nothing but make molds, with everything provided for his convenience. Molding machines in great variety are available for the most efficient production of different types of castings. In all but the smallest foundries the molds are poured and dumped with a minimum of human effort; the castings and sand are carried from one operation to the next on conveyors. In a modern sand system the sand is dried and put through a fine screen to remove metal and core butts, bentonite or clay and other additions are made, water is added to produce the proper temper, and then, after thorough mixing and mulling, the sand is transported to chutes at the molding machines. Molding sand so processed is of such quality that specially prepared facing sands are unnecessary.

MELTING EQUIPMENT. In the brass foundry, the melting operation is of first importance. Improper melting is the cause of many defective castings that are commonly attributed to bad molding or other causes. Five types of furnaces are in common use, and each of them is built in several sizes.

1. Crucible furnaces, in which the crucible is removed from the furnace and used for pouring into molds when melting is complete. In all other types, with negligible exceptions, the furnace is tilted to pour into a crucible or ladle. Furnaces of this type have been in use for centuries, with little change except in the adoption of modern fuels and more efficient combustion controls and in the improvement of crucible quality. They are still the cheapest and most convenient furnaces to be used in very small foundries or wherever operation is intermittent and a variety of alloys is handled in small quantities. Gas and oil are now the most common fuels, although coke and hard coal are in occasional use.

2. Crucible furnaces, in which the crucible is permanently installed in the furnace. Oil or gas is the fuel. More expensive to install than lift-out crucible furnaces and less flexible in operation, furnaces of this type are well adapted to production foundries of moderate size.

3. Hearth furnaces, in which metal is melted on a hearth by direct contact with flame and combustion gases. Furnaces of this type are available in a large variety of shapes and sizes, fired by oil or gas. They are commonly used in large-production foundries or in small foundries which have a steady production limited to a few alloys. Under such conditions their operating cost is low, and they lend themselves fairly well to mechanical handling of the metal and other labor-saving devices.

4. Hearth furnaces, in which metal is melted on a hearth by heat radiated from an electric arc. A motor-driven rocking mechanism thoroughly stirs the metal during melting. Furnaces of this type are of highly mechanized design and costly to install, but under favorable circumstances they show very low operating costs, and almost ideal working conditions. For best performance a dependable supply of electric energy at reasonable cost is necessary, and the foundry production must continue at a fairly high level. Intermittent operation is fatal to operating economy and to burden costs. In foundries depending principally on electric furnaces it is not uncommon to find one or more fuel-fired crucible furnaces or hearth-type furnaces to take care of peak production or to maintain production in slack periods. Hearth-type electric furnaces are particularly well suited to mechanized handling and are fairly flexible with respect to alloy changes. When necessary the furnace shell can be removed and a fresh one substituted in order to avoid contamination of the new alloy.

5. Electric induction furnaces, in which metal is melted by the flow of electric current through the metal itself, in a submerged induction channel which pumps hot molten metal into the main furnace chamber above. These furnaces also are costly to install and even more dependent than the arc type on continuity of production, since they cannot be allowed to cool and consequently require the continuous use of sufficient electric current to maintain molten metal in the induction channel during standby periods such as nights, Sundays, and holidays. Furnaces of this kind are particularly well suited to melting the high-zinc alloys such as manganese bronze. If run not less than 40 hours per week, their operating costs are reasonably low, but they are most economical if they can be operated in two or three shifts, 6 days per week. Electric induction furnaces are in satisfactory use on a wide variety of alloys including the high-copper tin bronzes and even some of the high-nickel alloys. Changing from one alloy to another is inconvenient.

OTHER FURNACE TYPES. Furnaces in less common use include cupolas, similar to those used for iron, electric hearth-type furnaces in which a radiant graphite resistor takes the place of the electric arc, crucible-type furnaces inductively heated by high-frequency electric current, and hearth-type furnaces in which flame and hot gases superheat molten metal on a hearth and then pass upward through a chimney into which the metal to be melted is charged from the top.

SELECTION OF FURNACE SIZE. With any type of furnace the melting capacity of individual units needs to be carefully matched with the foundry requirements for metal. The size of each unit should be such that, when metal is ready to be poured, it can be disposed of promptly, the furnace recharged, and melting resumed. Both economy of operation and a high standard of molten-metal quality are dependent on size of the units.

The bulk of nonferrous foundry work is in small castings in small flasks. The average weight of molten metal per mold is 12 to 20 lb. For a well-designed casting the temperature range within which satisfactory castings can be poured is about 150 F. Usually no more than 15 molds can be poured within this range from any one pot of metal before it becomes too cold. The best crucible or ladle capacity is 240 to 300 lb. Many foundries prefer 200 lb for very light work. If a 250-lb ladle is to be used, the furnace charge should be a multiple of 250. If there is only one pouring crew, the melting capacity of the furnace per heat should not greatly exceed 300 lb. For four pouring crews the proper furnace capacity is 1000 to 1200 lb. For a diversity of alloys the size of the furnace is limited to the weight of any one alloy that will be needed when the furnace is ready to pour.

Hearth-type furnaces, whether fuel-fired or electric, commonly have a molten-metal holding capacity about twice their rated melting capacity. When large castings are to be made this extra capacity can be used to advantage. For example, the molten metal in a 1000-lb furnace can be built up to 2000 lb or more by adding further increments of metal after the original charge has melted.

ALUMINUM-ALLOY CASTING

By W. P. Goepfert

Aluminum alloys suitable for casting are listed in Tables 2, 3, and 4 of Aluminum and Its Alloys, pp. 4-03, 4-04, and 4-05. The three most significant methods are sand casting, permanent-mold casting, and die casting. Die-casting alloys are listed in Table 6, p. 4-81.

18. ALUMINUM MELTING AND CASTING

MELTING. Pot furnaces of the indirectly fired gas or oil type using iron pots coated with a protective wash or nonmetallic pots of graphite or refractory are the most commonly used types for remelting for casting. The temperature of the melt should be kept as low as practicable, preferably below 1450 F, and the time a melt is held should be kept to a minimum to prevent excessive gas absorption and large grain-size development. The molten metal should be given only the minimum amount of agitation necessary to produce uniform composition. Fluxing is sometimes required to remove oxides and gas. For this purpose the agents most commonly used are aluminum chloride as solid flux, or chlorine or nitrogen as gaseous fluxes. To obtain the strongest, most ductile castings, pouring temperatures should be the lowest at which the mold can be filled without mis-runs or cold shuts. Proper arrangement of gates and risers will facilitate the use of low pouring temperatures.

Oxide entrapped in the molten alloys causes machining difficulties in the finished castings. These difficulties can be minimized by careful melting and pouring practices.

SAND CASTING. Large castings, such as crankcases for internal-combustion engines, transmission housings, engine blocks, and architectural castings, usually are made as sand castings. This process is also used frequently where the production lot is too small to warrant the expense of the steel or iron mold used in die or permanent-mold methods, or where the part to be cast requires intricate coring. The ordinary methods of molding with green-sand molds are employed, along with the good melting practices and good patterns necessary for the best results. Cores may be either green or baked sand with binders of oil, cereal flour, or synthetic resins. Ample gates and risers are necessary. Metal chills are sometimes used to avoid cracks and shrinkage and to minimize porosity in specific areas. Molding sands with high permeability are desirable to allow for the escape of mold gases.

Size Limitations. There is no inherent reason for weight limitations on sand castings. Sand castings range from an ounce to about 500 lb in weight, although castings weighing as much as 7000 lb have been produced. Although small castings having section thicknesses as thin as $^1/_8$ in. have been produced, $^3/_{16}$ in. is generally considered the practical minimum section for small and medium-sized castings.

Finish Allowance. For large castings an allowance of $^1/_4$ in. or greater should be provided for finishing. For small castings an allowance of $^1/_8$ in. is sufficient.

Tolerances. Thickness tolerances of $\pm ^1/_{32}$ in. can be maintained on small castings, but greater tolerances are required for larger castings.

Sand-casting Alloys. Nominal chemical compositions, densities, and typical mechanical properties are listed in Table 2, p. 4-03.

PERMANENT-MOLD CASTING. When the quantity of an article to be produced warrants the expense of the more costly mold, castings are often made by the permanent-mold process to obtain better mechanical properties, better finish, and closer tolerance than are obtained by sand casting. Automotive and diesel pistons, cooking utensils, fuel-pump bodies, washing-machine parts, and cylinder heads are typical examples of permanent-mold castings. In this process the mold is made of dense cast iron, and the aluminum alloy is fed by gravity. Where cores are required, they are usually of alloy steel except for semi-permanent-mold casting, where sand cores are used.

Size Limitations. Permanent-mold castings as heavy as 250 lb and semi-permanent-mold castings as heavy as 500 lb have been produced. The usual size, however, ranges from a few ounces to about 20 lb. Sections as thin as $^1/_{10}$ in. have been produced on some castings. The practical minimum generally accepted, however, is $^1/_8$ in.

Finish Allowance. Depending on the size of the casting, an allowance of $^1/_{32}$ to $^1/_{16}$ in. should be provided for finishing.

Tolerances. Thickness tolerances of ±0.010 can be maintained in some cases; however, a tolerance of ±0.020 in. is generally applicable.

Permanent-mold-casting Alloys. Nominal chemical compositions, densities, and typical mechanical properties are contained in Table 3, p. 4-04.

PRESSURE DIE CASTINGS. Where it is desired to obtain good reproduction of detail, surface smoothness, and dimensional accuracy without subsequent machining on a large number of the same small or medium-sized casting, use of the pressure die-casting method is indicated. In this process the molten metal is forced into a steel die, set up with steel cores as required, under air or hydraulic ram pressure depending on the type of machine. The commonly called "gooseneck" machine uses air injection developing pressures as high as 750 psi, 500 psi being the more usual operating pressure; whereas in the "cold-chamber" machine a hydraulic ram is used which develops pressures as high as 50,000 psi, a range of 3000 to 15,000 psi being more usual.

Size Limitations. Castings produced by this method are usually not very large, ranging from a fraction of an ounce to 20 lb. The limitation on size is governed by the capacity of the machine. Small castings having sections as thin as 0.035 to 0.065 in., and larger castings having sections as thin as 0.085 to 0.100 in. are normally producible.

Finish Allowance. Because of the good dimensional accuracy obtained by the die-casting method, subsequent machining is not usually necessary.

Tolerances. A tolerance of ±0.0015 in. per in. of dimension, ±0.002 in. minimum, is required on any dimension. For each additional inch over 10 in., this tolerance can be reduced to ±0.001. An additional tolerance of 0.010 in. (usually all plus) is required for dimensions across parting lines or other moving parts of the die.

Pressure Die-casting Alloys. Nominal chemical compositions, and typical mechanical properties are listed in Tables 6 and 7, pp. 4-81 and 4-82.

MAGNESIUM-ALLOY CASTING

By William H. Gross

Magnesium is most commonly cast by sand, permanent-mold, or die casting. Suitable casting alloys are listed in Tables 1 and 3, pp. 4-41 and 4-42. Other casting methods, such as precision investment (lost wax process), centrifugal, and plaster casting are also used commercially to some extent.

19. MAGNESIUM-CASTING PROCESSES

SAND CASTING. When relatively small quantities are involved, sand casting usually is the cheapest method. When parts are large or quite intricate in design, then sand casting is the only practical method. Natural and synthetic sands are both satisfactory for magnesium and should be as open as possible. The principal difference between magnesium sand foundry practice and methods used for other metals is that, for magnesium casting, protective sand addition agents are mixed into the molding sand to prevent reaction between molten magnesium and the steam generated in green-sand molds. A typical sand addition agent contains eight parts of ammonium silicofluoride and one part each of boric acid and powdered sulfur. The quantity of sand agent necessary in a green-sand mold will vary from 4 to 8% of the sand weight. Cores used for the production of magnesium castings should be resin bonded and as permeable as possible. It is desirable to have small amounts of sulfur and boric acid in the core sand; in addition, cores to be used in heavy sections should be sprayed with a solution containing a mixture of ammonium borofluoride, boric acid, and white talc in methyl alcohol. Chills are best made of cast iron, which does not alloy with magnesium and is cheap. A chill wash containing rosin and white talc in alcohol is sprayed on the chills to prevent blows. Vents and risers should be used generously in magnesium castings.

PERMANENT-MOLD CASTING. Iron molds are used for the production of castings when the quantities desired are sufficiently large. For magnesium, permanent molds can be considered when quantities approaching 1000 pieces are wanted. Both full and semipermanent molding equipment are used. Molds are coated with a mixture (colloidal clay and water glass in a water solution) to prevent too rapid chilling. This mixture is brushed or sprayed on the mold surfaces which have been preheated to about 400 F, after which the mold is ready for use.

DIE CASTING. When small castings are required in large quantities, the die-casting process usually is considered. Quantities of 1000 or more usually justify consideration of the die-casting process. Both cold- and hot-chamber methods have been employed on magnesium. The choice of method depends largely on design of casting, end use, and cost.

MELTING PRACTICE. Several melting techniques are used on magnesium, depending on the purpose for which they are used. Most sand casting employs the crucible process in which the metal is melted in steel crucibles with a protective and purifying flux that forms a crust on the top of the molten metal. Crucibles are heated in a gas- or oil-fired brick setting or in an electric pot furnace. Flux and chunks of metal are put into the hot crucible and are allowed to melt down together. When molten, the bath is thoroughly stirred with a circular motion to refine the metal, after which the flux and dross are skimmed off the top. Heating the bath to a point between 200 and 300 F above the melting point and holding it at this temperature at least 15 min prior to pouring is called *superheating*, and is done to refine grain size of the casting. Crucibles are lifted out of the setting and poured into the mold. Permanent-mold casting employs what is known as the *open-pot process*, in which a fluid-type flux is used and castings are poured by ladling the metal out of the pot. The die-casting process employs a still different melting technique in which the molten bath is protected by a dome containing sulfur dioxide to protect the metal from burning. Refining is done by means of a heavy flux which sinks to the bottom of the molten bath.

20. MAGNESIUM-CASTING DESIGN

SAND AND PERMANENT-MOLD CASTINGS. Magnesium alloys normally exhibit a shrinkage during casting of approximately $^{11}/_{64}$ in. per ft. Where shrinkage is restrained by cores, or on large castings, the shrinkage factor may be as low as $^{1}/_{8}$ in. Wall thicknesses of sand and permanent-mold casting should not be thinner than $^{5}/_{32}$ in. unless the area is very small. These thickness limitations are about the same as for most nonferrous metals.

Probably the most important consideration in magnesium sand-casting design is the avoidance of sharp corners. Generous fillets and radii should be provided. Holes should be beaded and section changes should be very gradual. Where a relatively thick wall or a large boss adjoins a thin section the thin wall should be gradually blended into the heavier section.

DIE CASTING. In general, the suggestions for a good sand and permanent-mold-casting design apply to die castings with one primary exception. Thin walls, which should be avoided in sand-casting practice, are desirable in die castings. Stiffness of walls can be obtained by ribbed construction. Allowance for draft should be great enough to allow castings to be readily withdrawn from the die. Undercuts should be avoided because they require loose pieces in the die and thus lower production rates.

One advantage in die casting is that parts can be cast with smoother surfaces and to closer tolerances than is possible with sand castings. Dimensions on the same side of the parting line of a die casting can be held to within plus or minus 0.005 in. per in. Dimensions which cross the parting line can be held to a tolerance of plus or minus 0.010 in. per in. Wall thicknesses should preferably be held within the range of $^1/_{16}$ to $^3/_{16}$ in. since maximum mechanical properties occur within this range. Walls as thin as $^1/_{32}$ in. are permissible if the area of such thickness does not exceed 10 sq in. A wall thickness as great as $^1/_2$ in. can be used on die castings which will be lightly stressed. External threads of 16 per in. or closer can be die-cast if the axis of the threads is in the parting plane. Internal threads or threads whose axis is not in the parting plane require loose pieces in the die which will slow up production. It usually is more economical to tap or thread in such cases.

ZINC-ALLOY CASTING

By G. L. Werley

Zinc alloys can be fabricated commercially by any of the common casting practices.

21. ZINC-CASTING PROCESSES

SAND CASTING. Sand-cast stamping dies made from wooden or plaster patterns, for drop-hammer forming, are used in the fabrication of aluminum, magnesium, zinc, stainless steel, and other sheet materials. They constitute the major production of zinc-alloy sand castings.

Unalloyed zinc was first used for these dies, but, later, alloys were found to be superior. The alloys with the greatest hardness and strength were the best. ASTM Alloys XXI and XXV (see Section 4, Article 28) are the ones used for drop-hammer work, and they produce ten to fifty times as many stampings as had been obtained from unalloyed zinc.

Since many of these dies, at the end of their production runs, are stored for the manufacture of replacement parts, ASTM Alloy XXV, with its greater dimensional stability, may prove to be more desirable than XXI even though its production record is slightly inferior to the latter alloy.

SLUSH AND PERMANENT-MOLD CASTING. Slush casting is restricted to the fabrication of hollow castings. The process consists of gravity-pouring molten alloy into a split mold (generally made of bronze) until it is filled, and then, almost immediately inverting it, so as to allow escape of unfrozen metal. The time required for this casting operation is sufficient to freeze a metal shell in the mold corresponding to the shape of the cavity wall. The thickness of the casting wall is dependent on the time interval between the filling and inverting of the mold and, to a lesser extent, on the chemical and physical properties of the alloy and of the mold.

Two zinc alloys are used for slush casting. One has a nominal composition of 5.5% aluminum with the remainder Special High Grade zinc. The other contains 4.75% aluminum, 0.25% copper, and the remainder Special High Grade zinc. The former alloy is readily slush-cast with the production of very thin walls, which tends to make its use popular from an initial-cost standpoint. However, unless the impurity limits are rigidly controlled, castings made from this alloy are susceptible to subsurface network corrosion and premature failure by warping and cracking. The latter alloy produces castings with improved mechanical properties and also with longer service life because of the protective effect of the copper addition. This alloy slush-casts with greater difficulty and produces castings with thicker wall sections. Therefore, the initial cost of the castings is generally greater than that for like castings made from the copper-free alloy. It is important to keep the composition of the copper-containing alloy under close control since increases in the aluminum content make the alloy brittle and decreases make the alloy sluggish.

The copper addition must be sufficient to afford the degree of durability desired, but should not exceed an amount which seriously affects production by causing excessive weight of the castings.

Permanent-mold casting differs from slush casting in that all the metal poured into the molds is allowed to remain there until it has solidified. The resultant castings are solid instead of hollow. The same two zinc alloys which are used in slush casting are also the only alloys used in permanent-mold casting.

DIE CASTING is the art of repeatedly producing accurately dimensioned castings by forcing molten metal under pressure into metal dies. All three types of die-casting machines—direct air, plunger, and cold chamber—can be used to prepare zinc-alloy die castings but economical practice dictates the use of the plunger machine.

In the production of zinc-alloy die castings in plunger machines the temperature of the metal should never exceed 425 C, or coarse-grained, low-shock-resistant castings will result. The preferred metal temperature range is 390 to 415 C.

The preferred range of die temperature for the production of die castings with the best surface finish, soundness, and mechanical properties is 150 to 220 C. When thermocouples are not used to indicate the die temperature it is possible to estimate the temperature from the appearance of the castings, run marks or cold shut marks indicate that the die temperature is too low and pits or blisters indicate excessive temperature.

The third major factor in the production of zinc-alloy die castings is the pressure applied on the metal. The pressure should never be less than 1500 psi. Lower pressures will result in low mechanical properties and in some unnecessary porosity in the castings. Higher pressures than 1500 psi are advantageous at times, but generally there is little to be gained by using pressures above 2500 psi. The velocity with which the metal enters the die is controlled by the pressure and the design of the die. The optimum velocity may differ for each casting, and the only way it can be determined is by trial and error.

Casting methods cannot be dismissed without some mention of the controls necessary for the maintenance of the composition of the three standard zinc alloys. Specifications for these alloys have been adopted by the American Society for Testing Materials (alloys XXI, XXIII, and XXV) and by the Society of Automotive Engineers (alloys 921, 903, and 925, respectively). (See Section 4, Article 28.) Only two of these alloys (ASTM XXIII and XXV or SAE 903 and 925) are in common use today.

In view of the limits of corrosion that must be observed for zinc-die-casting alloys, it is essential that analytical control be a part of the casting technique. This is especially true since lead and tin contamination is likely to occur at any time in a die-casting plant; aluminum is lost as a compound with iron in the skimmings when the alloy is overheated and magnesium is volatilized during fluxing.

Next in importance to composition and casting technique is employing a well-designed die. In die design, after the parting line and the general die construction have been planned, it is highly important to gate and vent the casting cavity properly. The gates and vents, as thick as can be tolerated, must be placed at their proper positions. In addition, large overflow wells should be connected to the cavity at the vent end of the die and at other places where there is a likelihood of trapping air. Since the loss of metal is small during the remelting of overflow wells, the cost of such wells is small, considering the improved quality. In most instances a saving actually results, because overflow wells accomplish a vast reduction in the percentage of rejected castings. Gates, vents, and overflow wells, considered collectively, have more influence than any other factor in the production of uniform high strength, good surface finish, and soundness in die castings.

PRECISION INVESTMENT CASTING

By F. S. Badger and W. O. Sweeny

Investment casting, or the "lost-wax" process as it is sometimes called, is a method of casting simple or intricate parts under controlled conditions so as to produce relatively accurate castings characterized by a smooth surface.

PROCESS. The process involves making a wax pattern in a die and then using this pattern to make a mold out of an investment material. The investment is a mixture of refractory particles and a liquid, which will pour and harden or set at room temperature. When the mold has set, the wax pattern is melted and burned out. Plastic patterns which vaporize when baked have been successful, but wax is the material generally used for production purposes. Parts made by this process, which vary from simple to complex designs, require a minimum of finishing and can be held to close metallurgical specifications.

MATERIALS. Practically all metals are suitable for precision-casting purposes including both ferrous and nonferrous metals, as well as highly alloyed metals. However, the process is especially suitable for expensive, hard-to-machine alloys that cannot be handled by conventional machining operations. Typical parts being manufactured in these alloys by the precision-casting process are turbosupercharger buckets, turbine blades, and turning vanes and axial-flow compressor blades for jet-propelled aircraft. Precision casting has also been used to produce such parts as reciprocating slides for cloth-cutting machines, fuel parts for aviation carburetors, pawls and claws for movie camera projectors, and also for rock drills, thread-chaser holder blocks, adjustment cams, and certain parts for diesel engines that require use of a high-strength corrosion-resistant metal.

22. METHOD OF MAKING THE MOLD

The first step in making the mold is the preparation of a die in which to produce a wax pattern. This die is usually metal, although rubber, plastic, and other materials are sometimes used. It can be produced in the same fashion as a plastic or die-casting die by direct machining from steel. However, the usual practice is to use a soft-metal die similar to the core box of ordinary foundry practice. Before the die can be produced it is necessary to make a master pattern.

THE MASTER PATTERN. The first operation is the preparation of one or more master patterns that are replicas of the parts to be produced. They are usually made about 1 1/2% oversize to compensate for wax and metal shrinkage, although this is not an exact figure and should be used only as a guide. Mastern patterns are generally made of brass, bronze, or stainless steel. In some cases, however, plaster and wood master patterns can be used, although neither of these materials is as satisfactory as a metal pattern. Where necessary, master patterns have core prints similar to those in conventional foundry practice, but it is not normally the practice to split master patterns for precision casting. Slight draft allowance is required to provide clearance from the die.

THE DIE. A two-piece die is made from the master pattern by placing the pattern on a wooden form which covers one-half of it. Plaster is then poured around the exposed half of the pattern and permitted to harden. The wooden form is removed, and a bismuth alloy is cast in a strong metal shoe over the half of the pattern previously in the board. When this is completed, the plaster support is removed; then, with the pattern still in place on half the die, the other half is cast in a similar shoe. The low-melting alloy cast has practically no shrinkage, and the die cavity produced is within 0.001 in. of the master pattern size. In order that the master pattern may be removed without harming the die, no undercuts are allowed; and a draft of about one-half degree is desirable on vertical surfaces in both halves of the die. A die is usually cast for several pieces instead of just one, since with more cavities each wax injection produces more wax patterns, thus providing faster and more economical production. When the die is completed and ready for use, it is clamped in a vise, which is water cooled to prevent any dimensional change as a result of the heat present during the wax injection.

WAX INJECTION. The wax generally used is a blend of microcrystalline waxes giving the desired properties of strength, ductility, and shrinkage. Two different blends of wax are used: one where toughness is the primary requisite: and the other, a more brittle type, for thin sections, where distortion might result if the tough ductile wax were used.

The wax is heated in a specially controlled furnace to a semi-molten condition. The temperature of the wax must be carefully controlled to within 5 F to obtain uniformity of size in the wax pattern. The actual temperatures and pressures used vary with different types of waxes, and with the shape and thickness of the part. Likewise, holding time in the die, rate of cooling, and other operating conditions will vary with the individual part.

After the wax has been brought to a molten condition, it is injected into the die. The pressure used varies with the size of the pattern, type of wax, and type of die. Obviously, a steel die will withstand higher pressures than a soft-metal die. Pressures used vary from 100 to 5,000 psi on injection machines. When the wax has solidified, usually in about one or two minutes, the die is opened and special knockout pins are operated to free the wax pattern so that it can be lifted out by hand. The die is then sprayed with a lubricant to prevent sticking and is ready for another injection.

ASSEMBLING WAX PATTERNS. Whenever possible, a group of wax patterns are joined together so that they can be placed in one mold. They are assembled by "wax welding" to the gates and risers. This is accomplished with the aid of a "hot wire welder," a short piece of resistance wire heated by an electric current to a low temperature—just hot enough to melt the wax. The gates and sprues are cast in the same manner as the wax pattern. The assembly represents the complete cavity in the finished mold.

INVESTMENT. There are two methods used in applying the refractory or investment materials.

(1) Mix and Pour Method. The assembly is surrounded by a metal box or cylinder, which is called the flask. This flask will retain the refractory mold-forming material as it solidifies around the patterns. A finely ground refractory containing some bonding agent is mixed with liquid chemicals or water and poured into the flask. Vacuum is usually employed to remove entrapped air. The mix solidifies somewhat like plaster of Paris.

(2) Dip Coat Method. This method employs a similar refractory as a thin coat on the patterns. Then this thin coat is backed up with a coarser, much cheaper material. The material cost is less, and the surface finish is generally finer, but the labor cost is more because of the two steps. The assemblage is sprayed or dipped in a fine silica powder suspended in a suitable medium, and somewhat coarser grains are screened or "stuccoed" to the dip coating. The fine material next to the wax provides a smooth finish on the casting.

The pouring mouth of the assembly is sealed to a steel plate and the stuccoed assembly thoroughly dried. A flask made of heat-resisting metal is then placed around the pattern and sealed with wax to the plate. The assembly must be liquid tight. The flask surrounding the patterns is next filled with a wet investment mixture made up of silica, sand, and crushed firebrick in a solution containing ethyl silicate, ethanol, and hydrochloric acid.

In both methods the filled flask containing this chemically hardening investment material is placed on a vibrator to pack the investment around the wax patterns and to make sure that all air is removed. This process is carried on until hydrolysis has taken place in a manner to set the investment mixture. After about one hour, the investment is gelled and the excess fines have risen to the top. The excess investment material is cut off with a saw, and the mold is allowed to age for about eight hours. At the beginning of the aging period the plate is knocked off the bottom of the mold, thereby exposing the pouring mouth into which the metal will ultimately be poured.

BAKING THE MOLD. The molds then are placed upside down in a furnace. In the preheating stage the wax is melted out, after which the mold is heated to a temperature of 1400 to 2000 F, any residue of wax being burned out as the temperature increases.

23. METHODS OF CASTING

The casting is usually done in some type of machine that will apply pressure to the metal, either centrifugally, or by pressure of a gas, usually air. For larger castings, gravity casting is used to some extent. Gravity casting is more economical than pressure casting and is just as satisfactory for simple castings. However, where complicated contours, shapes, serrations, and thin edges are involved, pressure casting is usually essential. Pressures ranging from 3 to about 30 psi, comprising the vast bulk of operations, can be applied by air. Where higher pressures are required they can be obtained by centrifugal casting.

The metal is melted by conventional means, usually in small indirect-arc or high-frequency induction furnaces. Generally, the indirect-arc furnace is used where the casting is to be made under gas pressure, and the induction furnace is used when the casting is to be made with centrifugal force.

GAS-PRESSURE METHOD. An accurately weighed charge of the desired alloy is melted under carefully controlled conditions in an indirect-arc furnace. Mold temperatures and metal pouring temperatures vary with the individual part and with the grade of alloy. Generally speaking, mold and metal temperatures are higher for thinner sections.

After the temperature has been checked, the heated mold is placed directly over the pouring spout of the furnace and is clamped in place. The assembly is rocked several times and then inverted so that the liquid metal runs from the furnace into the mold. At the time the metal is poured, air pressure is admitted into the furnace. The air pressure makes it possible to cast very thin edges and helps to produce sound and dense castings. The entire operation of bringing up the hot mold, clamping it into place, and pouring requires only a few seconds. Thus oxidation of the metal because of overcontact with air is avoided, and the flask will not cool off excessively and upset shrinkage calculations. The mold is then removed from the furnace and set aside to cool for about four hours.

VACUUM CASTING. Another casting method imposes atmospheric pressure on the casting by utilizing a vacuum on the mold. A vacuum line is attached to a chamber that is sealed to the bottom of the mold. Air and gases are drawn through the porous mold as the metal is poured in from a ladle to produce sound dense castings.

CENTRIFUGAL CASTING. The material to be cast is weighed and placed in a crucible that is then placed in a high-frequency heating coil. The charge is usually melted in 2 or 3 min, the actual time depending on the weight of charge and available power. Generally, a ratio of about 2 kw per min per lb is required. The crucible with molten metal is then transferred to the casting machine. If it is a horizontal machine, the metal is poured from the crucible or from a ladle into the central reservoir of the machine. If it is a vertical machine, the crucible itself is set in the machine; then the heated mold is inserted above the crucible and a cover plate is attached. The carrier revolves at high speed, and the centrifugal action causes the molten metal to flow to all extremities of the cavity.

FINISHING OPERATIONS. When the mold is cooled, the investment material is broken away from the casting by a pneumatic plunger. The casting is vibrated to loosen and remove the friable investment material between the nested finished pieces. Gates and feeders are removed, the gate areas are ground down, and any surface irregularities are removed by spot grinding. The ground castings are sandblasted, submitted to visual and dimensional inspection, and given x-ray and penetrative oil inspection when specified.

24. DESIGN OF INVESTMENT CASTINGS

The precision-casting process is, first, a means of producing shapes in steel or other machinable metals that cannot be economically made by other methods of manufacture, and, second, a means of producing intricate shapes in harder alloys that are difficult or impossible to forge, machine, or grind.

Parts made by the precision-investment-casting process do not compete on a price basis with parts normally made by screw-machine operations, or with forgings, coinings, stampings, die castings, or other simple castings that are readily machined.

Precision castings have been made in aluminum, magnesium, bronze, or other copper-bearing alloys, using plaster molds; but the following discussion is pertinent only to alloys with relatively high melting points. Closer tolerances, thinner edges, and other characteristics can be obtained under laboratory conditions or under circumstances where special handling is involved. The following specifications, however, reflect only what is commercially practicable at the present time.

TOLERANCES. The term *precision-investment-casting process* does not actually mean that castings will be held to fractions of a thousandth of an inch. Precision castings are held to close dimensions when compared with sand castings, but they do not compete with the tolerances obtained by precision machining or grinding. At present, ±0.005 in. per in. with a minimum tolerance of ±0.003 in. is commercially practicable. This means that to obtain a tolerance of ±0.003 in., the dimension in question must be 0.60 in. or less. These tolerances cannot be held across parting lines or on surfaces into which it is necessary to gate.

The yield of satisfactory castings is directly proportional to the dimensional tolerances allowed. The greater the tolerance, the greater the recovery, and, consequently, the lower the cost of any specific part. Since a price penalty must be put on close tolerances, all tolerances that are not critical should be widened as much as possible. For those surfaces where finishing operations are required, 0.010 to 0.030 in. of stock per dimension is satisfactory.

HOLES. Generally a hole that is small (up to $^1/_4$ in. in diameter) and shallow (approximately $^1/_2$-in. deep) can be held to a tolerance of ±0.003 in., both with respect to location (if dimension is 0.60 in. or less) and diameter. Larger or deeper holes require wider limits. Small blind holes cored with refractory material can be held to ±0.003 in. on diameter but not on location. Deep holes—except in hard, brittle alloys—can be successfully cored with refractory material. However, these close tolerances can be held only on holes that do not have a parting line. Since the elimination of parting lines in holes frequently necessitates loose cores, more handling is required and the cost of the part is increased.

The smooth surface common to precision-investment castings is partly the result of hand grinding to remove surface irregularities. These minor projections cannot be removed readily in small holes. Consequently, such holes frequently appear to be undersize when measured on a pin. For a hole that is to be used as cast, an allowance of a few thousandths of an inch should be made to compensate for this roughness.

Hole Finishing. If the cast hole is to be finished, this roughness will be removed at the time the hole is machined or ground to size. When the hole is cast "tap-drill size," the possibility of excessive tap wear due to the presence of small surface irregularities must be taken into consideration. With most alloys, it is advisable to plan to remove a small amount of metal by drilling or reaming so as to have parent metal exposed for the tapping operation. When a thread of 75% or less is required, the hole should be made slightly oversize to compensate for the surface irregularities.

Refractory Cores. When refractory material is used as a core, it gives a much smoother hole than if the hole is allowed to core itself with investment material. Refractory cores result in closer tolerances; however, this generally involves a slightly higher cost for the casting. The minimum-size hole that can be cored depends on the amount of surrounding metal. Thus a small hole that can be cored in a light section might not be practicable in a heavy section. The minimum-size hole that can be cored practicably is 0.050 in., even in light sections.

Special soluble wax can be used for holes when they are of intricate shape, or when the core cannot be withdrawn readily from the wax pattern because of a recess or some other structural detail. However, this procedure is fairly costly, and tolerances cannot be so close as when retractable steel cores are used.

WALLS. The minimum wall thickness practicable for production is approximately 0.50 in. for a uniform small section. But if there is sufficient taper to permit accurate feeding, it is possible to have a minimum wall thickness of 0.030 in. The tolerance on the wall thickness can generally be held to ±0.005 in. except when soluble cores are used, where a tolerance of ±0.010 in. is required.

EDGES. Approximately 0.012 to 0.015 in. is the minimum practical edge thickness, provided that everything else about the casting is favorable to the production of thin edges. To obtain the minimum thickness, it is necessary to have a gradual tapering rather than an abrupt sectional change. Moreover, it is not feasible to have a heavy section immediately adjacent to a very thin section. Thinner edges can be cast, but the recovery is generally lower and the handling problem is increased, with a resultant increase in cost. For parts subjected to high temperatures, a minimum edge of 0.025 in. is recommended. The thermal stresses created by the different rates of cooling between the thin and heavy sections are likely to crack edges that are too thin. Also, such edges are easily damaged in shop handling or in actual service.

The peak of serrations can be cast with a 0.005-in. radius, particularly with a fine pitch. The principal objection to casting serrations is the problem of eliminating small globules of metal in the root of the serration.

THREADS. Generally, it is more economical to thread parts by machining, tapping, or grinding than to cast them by the investment-casting process. Class 1 fits are the best that can be precision-cast. Unless a loose core is used, external threads will have a parting line. Internal threads do not have a parting line since the metal core chases the wax; but the cost is increased because the removal of the metal core from the wax pattern is fairly slow.

Globules of metal in threads are a serious problem, particularly in the threads of hard alloys, and it is difficult to clean them out satisfactorily by hand grinding.

In order to cast threads, the master pattern must have a pitch compensated for shrinkage. This allowance must be especially accurate, particularly on long sections, or the pitch of the thread on the casting will be incorrect.

SURFACES. Castings from investment molds generally have smoother and cleaner surfaces than those normally obtained from other types of molds. It is rather difficult, however, to obtain satisfactory castings of medium and large size without minor surface flaws. The larger and flatter the surface area to be cast, the greater the likelihood of obtaining small surface imperfections. The smooth surfaces are in part the result of hand grinding, which removes surface irregularities. Areas that cannot be readily ground will be rougher than the standard accepted precision-casting finish.

Both parting lines and draft are necessary in precision castings. The amount of draft should be as generous as permissible, yet can be as little as 1/2 degree per face. For the average piece the parting line is approximately 0.002 in. thick by 0.006 in. high.

The part should be studied so that the precision-casting manufacturer can be given the following information: (1) those surfaces which should be free from pits; (2) those surfaces into which it is not desirable to gate; (3) those surfaces on which no draft is permissible; and (4) those surfaces on which there should be no parting line.

Some applications, such as parts for gas turbines and food machinery, do not permit even minor surface pits; but, for many industrial applications, minor pits on one or more surfaces are acceptable. This information should be conveyed to the manufacturer so that the price will be based on the surface finish required.

SIZE. The size is limited primarily by the die. For cast soft-metal dies, current restrictions are a cross section of 10 in. by 5 in., with lengths of about 10 in.; but dies up to 20 in. long are feasible provided that the cross section of the part is much smaller. The die is not the limiting factor, however, when it can be machined from aluminum or other suitable metal. In such cases, the governing factors are the size of injection equipment, flasks, and other equipment.

WEIGHT of a precision casting is subject to size limitations. The maximum weight of an individual casting is dependent on the method of casting. For "pressure casting" in an indirect-arc tilting furnace, where air pressure is turned on after the furnace is inverted, the current maximum is approximately 3 $1/2$ lb. There is no minimum-weight limitation, provided that the casting meets the minimum requirements for thicknesses, hole diameters, and edges. A casting made by the conventional gravity-pour method has no weight limitations, but must be within the limits set by dies and molds.

FILLETS, which are frequently advantageous from a stress standpoint, are difficult to obtain by conventional means of manufacture because a square corner is normally obtained in milling or other machining operations. Generous fillets are definitely helpful in the precision-casting process, and with many parts they are almost essential. In addition, fillets are more readily cleaned by hand grinding than are square corners. At least $1/32$-in. fillet is desirable, and generally a $1/16$- to $1/8$-in. fillet is not excessive.

INTEGRAL CASTING. Often it is possible to combine two or more parts into one integral casting, thus eliminating assembly costs and frequently improving design. For this type of casting, two or more wax patterns are joined together, a single cast part resulting.

POWDER METALLURGY

By Claire C. Balke

25. DEFINITION AND SCOPE OF POWDER METALLURGY

Powder metallurgy is the art of making objects by the heat treatment of compressed metallic powders so that none or only a part of the mass is ever melted, and the shape of the object remains substantially unaltered, even though considerable shrinkage may take place. The two distinguishing features, pressing powders to shape and sintering below the melting point, have permitted this production method to supply special metallurgical and mechanical properties unobtainable by any other production process involving one or more of the many techniques of casting, forging, stamping, screw-machine operation, or the machining of cast or wrought metal.

The advantages of the powder-metallurgy method arise from the diversity of its applications to a number of different products, which may be grouped into the following three main categories as they appeared in industry.

1. SPECIAL METALLURGICAL PROPERTIES. The refractory, or high-melting metals, such as tungsten, molybdenum, tantalum, columbium, titanium, zirconium, and their alloys with each other, must of necessity be made by pressing their powders into bar form, sintering and hammering or rolling to massive and useful metal. No refractory crucibles are known which can be used commercially for melting these metals, and, indeed, the resulting properties of some of them, if melted, would make them unfit for their present uses.

The cemented carbide industry is built on the use of the powder metallurgy technique. Part of WC-Co composition melts and causes up to 20% linear shrinkage, although the parts retain all the details of their former pressed shape.

Metals which are immiscible in the liquid state may be intimately mixed in the powdered condition. Examples include tungsten-copper for welding electrodes and silver-graphite and silver-molybdenum for electrical contact points.

2. SPECIAL MECHANICAL OR STRUCTURAL PROPERTIES. No other known production method can give controlled porosity in a piece of metal. Porosity up to 50% by volume of interconnecting pores has made possible the porous-bearing industry. Other porous parts and available materials include metallic filters made from a variety of metals, tantalum condenser elements, and porous molybdenum.

Duplex structures include thermal strips which are made by pressing one layer of powder on top of another, such as iron and nickel, and then sintering and rolling to strip. The two metals are perfectly welded together so that use can then be made of their differences in thermal expansion.

Nonmetallics may be blended with metallic powders to give a friction material for brake linings. The metallic part dissipates the heat while the nonmetallic constituent supplies the frictional quality.

Insulated metallic powders are used extensively for electronic applications. Particles of carbonyl iron powder are so treated that when pressed together they are insulated from each other. This special structure is advantageous in tuning coils and cannot be made by any other production method.

3. ECONOMIC ADVANTAGES OVER COMPETING PRODUCTION METHODS. Many structural or functional parts are made by powder metallurgy in preference to the machining of cast or wrought metal because of economies which may arise from any or all of the following considerations: (1) reduction or elimination of secondary operations; (2) the saving of metal, which may run as high as 50%; (3) a tooling time which is often more favorable, and (4) many design features that can be used which are costly to machine by conventional methods. Tolerances and production rates may be other deciding factors in choosing the powder metallurgy process for making the part under consideration.

Many parts exhibit elements of all three of the main advantages described above. Although the first two are of prime importance in supplying special products, the third or economic advantage is the one that must be carefully analyzed before powder metallurgy is chosen as the production method to be used in making a part that might be possible to obtain by other means. Since success is so dependent on the design of the part, considerable attention is given to this subject in the following articles.

26. THE POWDER METALLURGY PROCESS

Although the process has permitted the growth of completely new industries, has successfully entered into competition with established methods, and has been employed in such a wide variety of applications, it may be reduced in all applications to a series of five basic operations: (1) preparation of the powder, (2) pressing, (3) sintering, (4) coining, and (5) finishing. These operations may be altered, repeated, or even rearranged on occasion to enhance metallurgical properties or yield desired results.

PREPARATION OF THE POWDER. The great majority of elemental powders are prepared by one of two methods: electrolysis or reduction of an oxide. While other methods may be used to obtain special particle shapes or alloy powders, the great bulk of commercial powders is made by either one of these two methods. The blended powders may also include nonmetallic constituents. In most cases they are lubricated to assist in the second step of pressing them in a die. The powders are closely controlled as to purity, particle size, flowability, compacting factor, and apparent density. The last three characteristics are important factors in the use of a powder in high production presses and must be known by the die designer if the part is to be made satisfactorily.

THE PRESSING OPERATION is the most distinguishing characteristic of the powder-metallurgy process. Pressures range from only a few tons to as high as 50 tons to the square inch. Pressures up to 100 tons total capacity can be had on automatic mechanical presses operating from about eight to several hundred times a minute, depending on the size, complexity of part, and the type of powder used. Pressures above 100 and up to 3000 tons total capacity are obtained in the slower-acting hydraulic presses which may or may not be automatically fed with powder.

Dies. Hardened-steel dies are most commonly used and will yield up to 150,000 parts before wearing out of tolerance. For more abrasive powders and where parts are needed in greater quantities, it is often more economical to line the die cavity with hard carbide inserts shrunk into a steel case. Production often runs over a million parts before such a die wears out of size. It is obvious that the dies and punches must be designed to withstand the heavy pressures. They must also have sufficient capacity to hold the voluminous powder which generally has a three-to-one compacting factor, so that the final part is only about one-third the height of the powder fill. Most dies are flush filled by a powder hopper which vibrates over the die cavity and, as it sweeps aside, levels the top surface of the powder flush with the surface of the die.

Practically all metal powders, with the exception of the very soft powders such as lead, have little or no hydrostatic character even under the great loads applied. Sometimes it is possible to lubricate the die walls before each fill to reduce die-wall seizure which causes cracking when the compact is ejected. All compacts expand slightly when the pressure is released and they are removed from the die. Cracking difficulties arise more often with hard powders such as tungsten than with more ductile powders such as brass.

The size, complexity of design, and material of a given part must be carefully considered before the powder metallurgy method is attempted in its production. The main limitation lies in the pressing operation because of the cost of massive equipment needed to give high production at high unit pressures, and the comparative lack of flow in the mass of powder while under pressure.

Figure 1 illustrates the details of the pressing operation for a simple cylindrical part having a flange and a center hole. The operation is divided into four main steps, as follows: (*A*) The die cavity is flush filled by a hopper to a depth approximately three times the height of the compact. The essential punches, Fig. 1*A*, consist of an upper punch which has a hole to fit over the stationary core rod, a lower stripper punch, and a lower center punch. (*B*) The top and lower punches move toward the center of the compact to give as uniform a density as possible. (*C*) The lower punches move together to start the ejection of the part. (*D*) The stripper punch stops flush with the die as the center lower punch continues the ejection to free the part from the die, at which time it is swept aside by the hopper containing the powder, and the cycle is repeated.

It is obvious that die-wall friction must be considered in the design of the part as this directly affects the density to which the powder may be pressed. The density in turn affects the properties of the part to a greater extent than any other single factor. The greater the side-wall area compared to the sectional area, the lower will be the density and the poorer will be the physical properties.

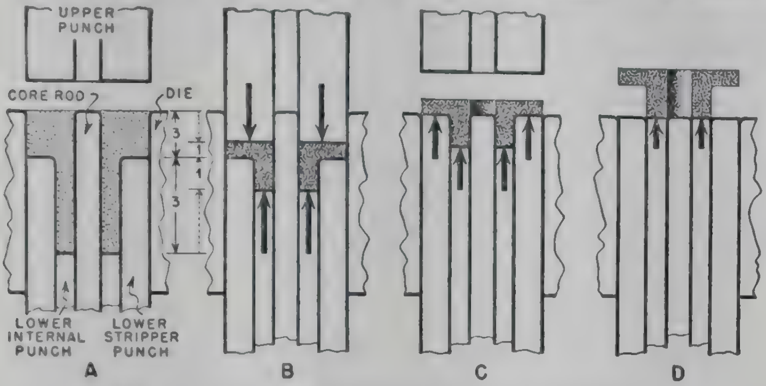

FIG. 1. Four stages in pressing a part from metal powders.

SINTERING may be done in ordinary brazing furnaces with controlled atmospheres or in highly specialized vacuum furnaces. The temperature is chosen so that either no melting takes place or only a chosen portion of the composition melts. In many instances the dimensions of the pressed part can be retained with practically no shrinkage taking place during the sintering operation. In other instances, especially where part of the composition melts, considerable shrinkage may take place and the part must be pressed oversize by a predetermined amount. Cemented carbide compacts suffer as much as 20% linear shrinkage when the binder portion melts to cement the carbide particles together. For many powders no further heat treatment is required. For others a second pressing and a second sintering are required to attain optimum physical or metallurgical properties.

COINING of a part is resorted to when tolerances must be held to close limits or the surface must be made smoother. This often relieves the necessity for too close dimensional control in the original pressing and sintering operations.

FINISHING, or secondary, operations include the use of one or more of those metallurgical or shop practices required to add features not supplied by the preceding powder metallurgy operations. They may include deburring, rolling, heat treating, or machining. Coining is sometimes classed as a secondary operation, but it is so common to the practice of the powder metallurgy method that it is here classed separately.

27. ECONOMIC ASPECTS OF POWDER METALLURGY

In those industries where powder metallurgy supplies some very special metallurgical or structural advantage, the economic aspects are of secondary importance. When the method is applied to metals and products already established, it must compete with the established procedures for making cast and machined products. While it cannot compete at every turn with all the products of precision casting and stamping methods, it does find a broad field of economic application in the manufacture of parts formerly made by these methods.

Powder metallurgy allows tolerances of 0.001 in. to be maintained. At higher costs, dimensions may be held even closer. Savings in metal are realized by the elimination, to a great extent if not completely, of all machining. Often a part will weigh only half as much as the original blank if much machining has to be performed in its manufacture. The surfaces of powder-metallurgy parts are very smooth and require no finishing although deburring may be needed, especially if high pressures are used in forming the part.

Metal powders cost more per pound than massive cast metals. However, savings resulting from the elimination of machining offset the differential somewhat, especially with nonferrous materials.

The quantity of a given part is a determining factor in the choice of the powder-metallurgy method. Small runs raise the cost out of proportion to the value of the part. Usually the quantity should exceed 50,000 pieces in order to reduce the relatively high die and pressing costs to a reasonable figure.

In contemplating the possible use of this production tool for manufacturing a given part, careful consideration should be given to all the factors, including die cost, number of pieces, tolerances, physical and mechanical properties, tooling setup time, and value of the part. Powder metallurgy is not a panacea for all metallurgical and machining problems. It is supplementary to the older production methods.

28. DESIGN OF POWDER METAL PARTS

The design of a part, even for the older applications of the powder-metallurgy method, is a deciding factor in the successful application of this method of manufacture. It has been found that density affects the properties more than any other single factor. When

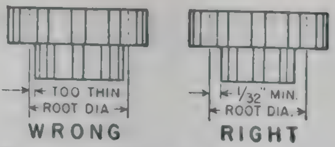

Fig. 9. Extension of the step correction of Fig. 8 to a cluster gear in which the major diameter of the smaller gear should be appreciably smaller than the root diameter of the larger gear.

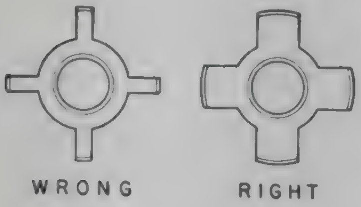

Fig. 10. Thin projections, such as splines, offer difficulty in pressing because of friction due to large die wall surface compared to cross-sectional area. More difficulty is encountered in sintering when warpage takes place.

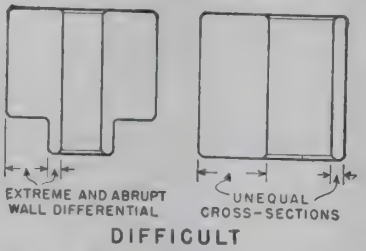

Fig. 11. Abrupt changes in section give the same warpage and shrinkage difficulties as Fig. 10.

powders are pressed in a die, they do not act hydrostatically. Because considerable friction results as the powder is pressed against the die wall, the density will be lower toward the center of the compact, with resulting lower strength. The design of the part should then take into account the ratio of wall area to the cross-sectional area against the punch, and this ratio should be kept as low as possible to obtain the highest density.

The designing of many parts by a number of manufacturers in the industry has resulted in certain practices which have become more or less standard. They are illustrated in Figs. 2 to 13. The design features may be grouped into four main types.

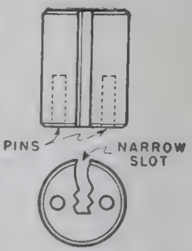

Fig. 12. Thin pins on punches to make blind holes and odd-shaped hollows which must be made by core rod or die are weak features in die design and should be avoided.

1. FEATURES WHICH MUST BE MACHINED into the part after the powder-metallurgy operations have been completed include holes not parallel to the direction of pressing, re-entrant angles, undercuts, threads, and certain tapers, counterbores, and hubs (Fig. 2). On the other hand, if properly used, some tapers, counterbores, and hubs can be made by powder metallurgy (Fig. 3).

2. SHARP CORNERS, RADII, FEATHER EDGES, BEVELS, LANDS, CHAMFERS, EDGES MEETING, AND STEPS must all be handled in special ways. In Fig. 4 the step should have a radius to prevent wear on the edge of the punch. Unless a chamfer and land are specified, the top punch will leave a square corner with a possible burr. A radius at this corner would require a feather edge on the punch. Figure 5 shows the corrections to be applied to punches with feather edges and the meeting of two punches. A curvature of too great proportions weakens the punch if heavy pressures are used. Figure 6 shows the application of chamfers and lands to avoid sharp corners and burrs. Figure 7 applies the land to a bevel, and a radius and severe taper to a counterbore, to permit easy removal of the part from the punch. In Figs. 8 and 9 steps should be not less than about $^1/_{32}$ in. so that a stripper punch can be used. If not used, the corner of the part tends to break off in the absence of exceptionally heavy tapers.

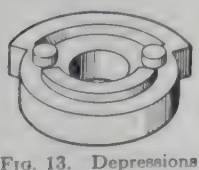

Fig. 13. Depressions and bosses can be made on punch faces, but they should be as shallow as possible and generously tapered.

3. NARROW PROJECTIONS such as splines, and abrupt changes in thickness or section, are not only difficult to press but offer their greatest trouble in warpage and non-uniform shrinkage in the sintering operation. Figure 10 shows the usual correction for thin projections. Figure 11 emphasizes the difficulty in thickness and section changes. Figure 12 shows the difficulty of thin pins in the punch or core rod as well as a thin slot which would have to be incorporated in the die or punches. These weak members of the die and punch assembly cause expensive maintenance.

4. DEPRESSIONS AND BOSSES can be made on the punch face but they should not be very deep and should have considerable taper to permit easy withdrawal from the punch face (Fig. 13).

29. PROPERTIES OF PARTS MADE FROM POWDERS

Powder-metallurgy parts, which are in competition with parts made by other methods, do not have the properties of wrought metal but often are superior to cast properties, depending of course on the degree of density attained in the powder-metal parts. Those powder-metal parts, which supply some special metallurgical feature such as a duplex or a porous structure, are unique and have no competing methods.

Each manufacturer of parts has developed his own techniques to achieve certain physical properties which are constantly being improved. The designer is therefore referred to them for more exact data. It must be emphasized, however, that the mechanical properties are more dependent on density than on any other factor, and that density in turn depends more on the shape and method of pressing than on any other single factor. It is advisable to compare the wall area to the pressing area of the part in question. This ratio is referred to as the W/P ratio. For a cube it would be 4 : 1. When the ratio rises (long parts pressed on end), the density decreases; when it is smaller (flat parts) the density is higher for the same operating conditions. In addition, the density of a given part varies, being highest near the face of a moving punch and lowest near a stationary punch. Comparing the density of a section taken from a part, with the physical properties plotted against density for the same material, will give a rough approximation to the lowest value of these properties in the part.

The materials generally used for powder-metallurgy parts include iron, with or without various amounts of carbon and with or without impregnation with copper, and brass, bronze, or copper, either alone or mixed with graphite flakes. The other important powders constitute only a small percentage of the total weight of powder used. They include powders for cemented carbides, contact materials, refractory metals, and electronic applications. Some use of aluminum powder has been reported, but as yet its use is not widespread.

PLASTIC WORKING OF METALS

Plastic working of metal, by force of pressure, changes the form, shape, contour, or cross section of an original shape into a preconceived and desired shape. By contrast, the whittling operations of machine tools change an original shape by removal of metal. The principal processes for plastic working of metals are *forging*, *forming*, *drawing*, *shearing*, *extruding*, *rolling* and *spinning*. Original shapes used for plastic working are *ingots*, ***blooms***, ***billets***, ***bars***, ***plates***, ***sheets***, ***strips***, **and** ***extrusions***.

Plastic working of metal may be performed hot or cold. The distinction is whether the metal is to be worked at room temperature or whether it is to be heated to a high temperature preparatory to working. At room temperatures, metals are worked below their recrystallization temperatures. When heated preparatory to working, the metals are worked, usually, above their recrystallization temperatures, where slip-plane distortion through the crystal is corrected at once by what is considered to be spontaneous annealing, and the crystal structure is unstrained on completion of the work. Actually, some working strains may remain in parts hot worked or forged and are removed by suitable normalizing or annealing operations. Cold working of metals causes cumulative strain hardening, and after strain hardening in one or a series of operations the metal must be annealed to restore an unstrained crystal structure for further cold-working operations. Normal cold-working processes, *shearing* (*blanking*), *stamping*, *drawing*, and *forming* are considered in a subsequent chapter of this section. Normal hot-working processes are *forging*, *mill rolling*, and *extruding*. Plastic working of metals by forging is considered in the following chapter, mill rolling and extruding are beyond the scope of this Handbook.

FORGING

By Eugene C. Clarke and Waldemar Naujoks

Forging performs changes in shape and/or of cross section by use of powerful pressure from a hammer or press on metal which has been heated to its plastic range. The normal plastic range for steels and high-strength alloys is from about 1900 to about 2300 F; for brasses and bronzes, from about 1100 to about 1700 F; and for aluminum and magnesium alloys, from about 650 to about 900 F. At the elevated temperatures the amount of work performed on the metal is almost unlimited, except by the capacity of the part to hold temperature at the most suitable temperature working range. The forging processes are further influenced by the characteristics of the metal being forged and by physical and mechanical limitations of the equipment employed for the plastic deformation. Hammers and presses used are generally very rugged and powerful. Forging metals, iron, steels, and nonferrous alloys, are identified and described in Sections 2, 3, and 4.

Forging operations may be considered in two general groups, (1) smith die forging (flat die) and (2) impression die forging. Smith forging work includes cogging of ingots, drawing out bar stock, die block forging, weldless ring forging, and general smith forging. Impression die forging includes forgings produced by the use of impression dies where quantities of forgings are produced as commercial duplicates of each other. Impression dies are sometimes known as closed dies.

ENERGY REQUIRED. If, in mechanical forging, E represents the forging energy, V the velocity of impact of the forging element of a mechanism, and W the weight or force applied, $E = WV^2/2g$. From this it is readily appreciated that the weight or pressure applied must be greater than the affected mass of the forging and that, with the size of the forging placing a practical limitation on mechanical equipment employed, the classes of forging equipment are economically complementary rather than competitive.

The rate of plastic flow of the subject metal at forging temperature limits the amount of deformation per operation and governs the application of forging power. If deformation is accomplished beyond the rate of plastic flow, rupture of the metal occurs. The rate of plastic flow varies with the subject material, its form and density, its temperature during the forging operation, and the velocity and continuity of power application.

LIMITATIONS. This discussion is confined to consideration of actual forging applications. It, therefore, cannot include details of heating, shearing, heat treatment, etc., but a few characteristics of the metal being forged exert influences common to all procedures and are briefly mentioned.

During all forging operations the metal is cooling. Hence its fluidity for plastic flow is being reduced. Thus the duration of any forging operation is limited, the limitation varying further with the kinds of metal being forged. The forging dies are extracting heat from the forging in proportion to the time in contact with it and the amount of surface contact area with relation to the bulk.

When the forging is larger in the area to be deformed than the impinging or contacting dies, as in cogging down an ingot, the forging effect is reduced by the resistance to distortion of that part of the metal not in contact with the dies of the forging mechanism. The deformation is necessarily limited in scope to that which will not cause laps at adjoining forged areas and which does not shear the metal at those sections under the edges of the dies.

When the forging is smaller in area than the die face, a limitation on height is introduced. Generally, the greater the area on which the dies impinge, as related to the height between impinging dies, the less is the control of plastic deformation, with the limitation that the distance between the dies at the point of impact cannot safely be greater than three times the smaller sectional dimension. When the height limitation is exceeded, the forging frequently will bend, forming a lap, rather than follow the desired plastic deformation. The hammer with high impact velocity is effective on thin stock which is unworkable in a press, and the press is more effective on relatively thick sections. The difference in metal flow under the two tools can be observed at the ends of sections reduced by forging (Fig. 1). That reduced under a hammer will have the edges extending beyond the center; that reduced under a press will have the center extending beyond the edges.

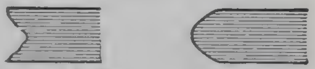

Fig. 1. Metal flow—presses and hammers.

FORGING PRESSURE. The force of forging pressure may be one of three kinds: (1) impact pressure, a high-velocity pressure as imparted by the hammer; (2) push pressure, a low-velocity pressure as imparted by the hydraulic press; and (3) a combination of impact and push pressure as imparted by the modern high-speed mechanical forging press.

Impact pressure (high-velocity pressure), as given by the forging hammer, is dependent on the velocity and weight of a falling mass on the work. The maximum potential energy is available at the instant the falling weight touches the work, and as the impact pressure exerts its energy on the metal to change its shape, the weight is brought to rest, expending all its available energy. The weight is raised, and again falls for the succeeding impact blow. One, several, or many blows may be required to complete the forging. If the hammer blows are of sufficient rapidity, advantage is gained of the momentum of metal flow, and a greater rate of flow is attained than with blows at greater intervals.

Push pressure (low-velocity pressure), applied and maintained in motion hydraulically, is limited by the metal's resistance to flow, the increased density of the metal between the dies, the friction between the dies and the work, and the increasing resistance to flow caused by reduction in temperature during the forging operation.

Combination impact and push pressure is developed through eccentric crank motion in the modern high-speed mechanical forging press. On the forging stroke, the pressure increases in magnitude as the work is being deformed while the velocity of stroke decreases. At the end of the forging stroke, maximum pressure is exerted and the velocity is nil for an instant. High-speed mechanical forging presses are used almost entirely on impression die (closed die) forging work.

1. SMITH FORGING

Smith forging, or flat die forging, includes the broad field of forging work produced between flat-faced dies and possibly supplemented by stock tooling, the final shape of the forging depending largely on the skill of the smith for size and shape. This type of forging work dates back through the centuries, when anvil and hand sledges were the only means of shaping metal. The present design of hammer and press forging equipment had its inception in comparatively modern times, beginning with the Naysmith Steam Forging Hammer in 1838. Present forging practice makes use of small to large power forging units which include helve and trip hammers, steam hammers, and hydraulic forging presses. Much of the large forging equipment is used in cogging large cast ingots into blooms and billets, into drop forging die blocks, and into large shafts, cranks, blocks, plates, ship rudder frames, and large weldless rings. Medium-sized forging units work billets into bars, large square and hexagon nut blanks, wrenches, shafts, trunnions, and weldless forged rings. Small power hammer units forge hand tools, chisels, drill points, tongs, hooks, clamps, tool bits, and dress tools. Shapes are approximate in most cases, and the finished shape is obtained by partial or by overall machining.

POWER HAMMERS. All power hammers employ the same general principle of operation, a falling weight striking the blow, with the entire energy being absorbed by the work. Where further blows are necessary, the striking weight is raised for the succeeding blow. Some hammers employ only a gravity fall, the energy delivered on the work being the product of the weight of the hammer head and the distance of the fall. Other hammers increase the striking velocity of the hammer head by mechanical means. The size rating for any power hammer is given as the weight of the striking parts. The helve hammer and the trip hammer are in the small power hammer group, with their striking weights ranging from about 15 to about 500 lb. Hammer strokes range from about 400 a minute for small sizes to about 175 for large sizes. Double-acting power hammers, commonly known as steam forging hammers, though many are operated on compressed air, produce the largest amount of smith-forged products. Steam or air pressure is used to raise the striking weight and to increase the velocity on the striking stroke. Steam pressure at the hammer is usually 90 to 100 psi, and air pressure is usually 80 to 90 psi. Rated sizes of steam forging hammers range from about 800 to approximately 16,000 lb. Some

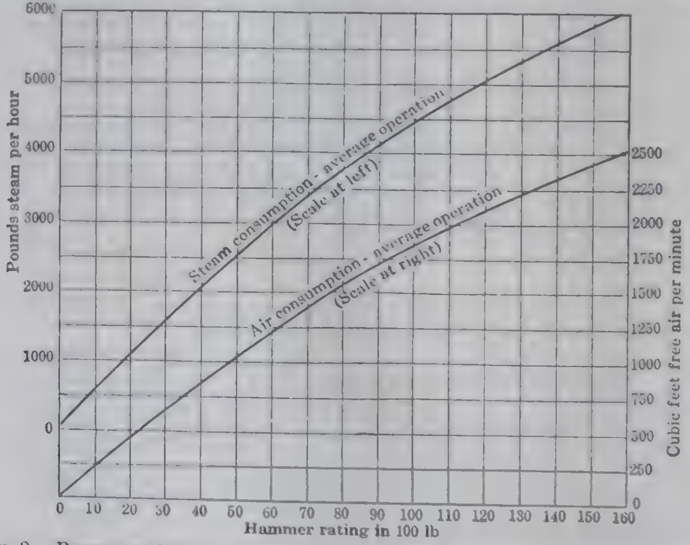

FIG. 2. Power requirements, steam- and air-driven hammers, for flat die forging.

of the newer types in the small and medium sizes are operated on compressed air, with the air compressor being built inside the hammer frame. Recommended hammer sizes for the nominal sizes of forging stock are shown by Table 1.

Power consumption of double-acting hammers varies with every job, and when several hammers are served by a single power plant the stand-by requirements are materially reduced. Figure 2 indicates the stand-by requirements of a single hammer for normal operation. For a group of six or more hammers, the stand-by requirements are frequently reduced 60%. No general data on power consumption are reliable, and the manufacturer should be consulted for specific information.

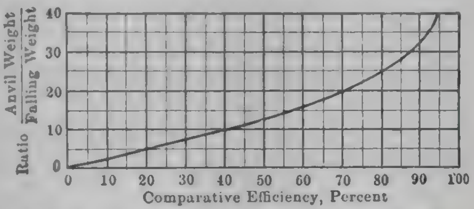

FIG. 3. Comparative efficiency of anvil ratios.

Weight of the anvil as compared with the weight of the falling parts has a marked effect on the amount of forging accomplished per blow. Figure 3 shows the relative efficiency of various ratios of anvil weight to falling weight. It has been found that a 15:1 anvil is the most economical for this type of hammer.

FORGING PRESSES for smith forging work are usually of the hydraulic type, with either steam or electric motors being the primary source of power. Intensifiers are employed to raise basic steam or pump pressure to high pressures in the operating cylinders, these being raised as high as 6000 psi. Hydraulic forging presses commonly range in sizes from about 250 tons forging pressure to about 10,000 tons forging pressure.

2. IMPRESSION DIE FORGING

Commonly known as die forging or drop forging, impression die forging makes use of cavities in alloy steel dies to produce forged shapes in quantities, the finished forgings being commercial duplicates of each other. In addition to the final or finishing shape, impression dies may contain preliminary shaping steps to permit the change from the original forging stock to the finished forging without mechanical defects. The number of forging steps necessary to produce the finished forging in the impression die is dependent on the size and shape of the part, on production quantities, and on the kind of material being forged. When impression die forgings are made on the drop hammer, they are correctly called drop forgings; products of the forging machine or upsetter are called machine or upsetter forgings; and when the forging press is used, the forgings are called press forgings. All forgings made by impression dies are considered impression die forgings. Generally, where the forging can be made by either of the several methods, the quality is comparable, and the choice is made for economic reasons.

DROP HAMMERS. Two types of drop hammers are in common use for drop forging in the United States, the gravity type usually known as the board drop hammer, and the double-acting type generally called the steam drop hammer. The gravity or board drop hammer depends on the free fall of the ram and die for its impact pressure. The ram is raised by maple boards fastened to the top of the ram, by rolls in the head of the hammer. All blows are of uniform intensity and the hammer is operated by a foot treadle. The double-acting steam drop hammer (sometimes operated with compressed air) uses steam or air pressure to raise the ram and to increase the velocity of the striking blow. The force of the blow can be regulated from a light tap to the full blow at the will of the operator. The foot treadle is used on small and medium-sized units, and hand levers are used on large units. Board drop hammer sizes range from about 200 to about 7500 lb, and the height of fall is about 30 in. for small sizes to about 60 in. for large sizes. Steam drop hammer sizes commonly range from about 1000 to about 50,000 lb. The force of the full blow of the steam drop hammer is more than two times the blow given by a board drop hammer of equivalent rating.

Hammer Foundations. Because of the shocks produced by drop hammers in operation, the importance of proper installation for the foundation cannot be overemphasized. For a given forging hammer, size and bearing area of the concrete foundation depend on the nature of the soil. Oak timbers are used for cushion between the concrete and the base of the anvil. Special pads are used sometimes to try to dampen vibration effects. A recent foundation designed to eliminate vibration is a spring suspension type, where a heavy concrete block with the drop hammer rests on a series of springs. Well-designed foundations with proper installation insure the highest production, lowest maintenance costs, and freedom from shock transmission to surrounding structures.

Power Required for Deformation. No generally accepted method or formula exists for predetermining the power required to deform metals in the forging hammer. Many tests on sample shapes under varying conditions have been made from time to time by individuals and groups, but the variables are so many and so little is known of strains beyond elastic limits that the practical application of formulas has not been developed. Size, shape, bulk, cross-section variations, material composition, plastic temperatures, forging temperature range, and type of forging hammer are some of the variables that influence the power and speed required for drop forging.

In the laboratories of the Chambersburg Engineering Company, Chambersburg, Pa., tests have been made in a specially constructed apparatus which, with varying falling weights, velocities, and anvils, simulates all conditions met in current practice. Not only are temperatures accurately controlled, but the rebound of the impacting die and the motion imparted to the entire structure also are measurable. Although useful data for designing hammers have been developed, all are empirical and incapable of reduction to formula. Three very useful points were established, however, in the research conducted to the end of year 1947. (1) Within the range of present hammer velocities there is practically no difference in work accomplished by different falling weights and varying velocities to give the same available energy. Hence, within reason, it is desirable to forge on large rather than small hammers to save time and heat by shorter strokes. (2) The speed of forging can be increased beyond current practice as hammer construction is developed to control such speeds. (3) The work done per blow is definitely related to the ratio of falling weight to anvil weight. Figure 3 shows the relative efficiency of various ratios of anvil weight to falling weight. Ratio of falling weight to anvil weight of 20 : 1 or greater is standard practice for drop hammers.

Power Consumption of Drop Hammers. Gravity drop hammers whether lifted by direct-connected motors, by belts, or by steam or air use energy only to lift the falling mass. Hence the speed of the lift and the friction within the mechanism readily indicate the power requirements. It is common to calculate 1 hp per 100 lb of rated falling weight. Manufacturers of the various types of gravity drop hammers should be consulted for specific information.

Steam and air-driven hammer power consumption is shown in Fig. 4

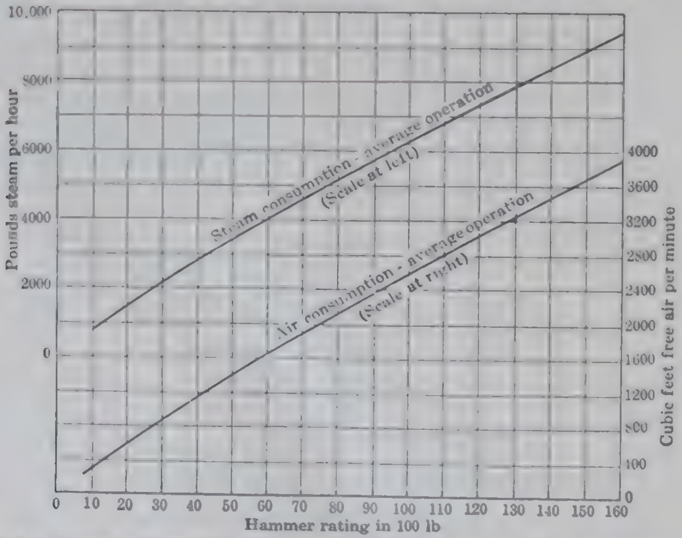

FIG. 4. Power requirements, steam- and air-driven hammers, for drop forging.

Trimming Presses. Drop hammer forgings require trimming to remove the flash. Crank-driven power presses are generally employed. For hot trimming, such presses are provided with a side shear for cutting the sprue, or stub end, from a bar.

MACHINE FORGING. The displacement of metal in closed dies, one of which is reciprocated by a crank mechanism, is plastic flow induced principally by upsetting and by piercing, or by both, for the mass production of identical shapes. Since each operation fills the die cavity under high hydraulic-like pressure, the stationary, or *grip*, dies are split to permit placing and extraction of the stock. The grip dies hold the stock, by frictional grip, against the forging force of the heading tool. Bar stock normally is used, and successive deformations to complete the shape are done in multi-impression dies. Positioning stops for each impression and a *cut-off* to shear the finished forging from the bar are provided.

The plastic flow engendered in machine forging is illustrated by Fig. 5, wherein both upsetting and piercing have contributed to the desirable internal structure. In properly designed dies, the stock is plastically flowing under compression in all impressions, resulting in a radial grain flow and refinement that is essential to a great variety of forgings, such as gear blanks and bearing races.

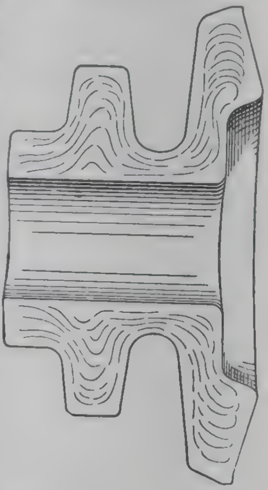

Fig. 5. Grain flow in machine forging.

DIES. E. R. Frost (Ref. 1) gives three rules as follows: Let d = diameter of bar. (1) The limit of length of unsupported stock that can be gathered or upset in one blow without injurious buckling is not more than $3d$. (2) Lengths of stock more than $3d$ can be successfully upset in one blow, provided the diameter of the upset made is not more than $1\,{}^1/_2\,d$. (3) In an upset requiring more than three diameters of stock in length, and in which the diameter of the upset is $1\,{}^1/_2\,d$, the amount of unsupported stock beyond the face of the die must not exceed $1d$.

The dies in a forging machine must resist pressure, abrasion, and heat. In automatically fed machines, the drawing of the temper of the dies generally reduces the forgings per dressing well below the number of forgings secured per dressing when hand fed. Cold-heading operations, as used in forming rivet heads, enjoy the longest die life. High chrome-nickel or vanadium steels, or other alloys, which retain their characteristics at relatively high temperatures are desirable when large radiation surfaces occur in the forming operation. Before being put in service, dies should be checked for hardness, which should conform to the requirements of the particular operation while avoiding excess hardness that may introduce brittleness. Figure 6 indicates practical selection of die steels. *Metals Handbook*, 1948 edition, should be consulted for details regarding the selection and heat treatment of dies for machine forging, cold heading, etc.

FORGING MACHINES. Requirements of the modern forging machine are: grip sufficiently tight to prevent die separation and consequent fins; maintenance of alignment in both the gripping and upsetting mechanism to insure concentricity and to avoid breakage of punches; rapid starting and stopping; ease of control by the operator. Of major importance is the rigidity of the frame enclosing the mechanism. It must be extremely massive, and currently is made of a single steel casting, heat treated and prestressed with heavy steel bars, shrunk in place. Commercial forging machines are nominally rated in inches of stock, a rating which usually requires interpretation by the builder.

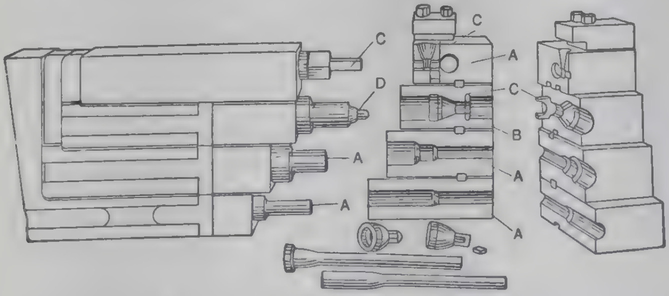

Fig. 6. Die setup for forging machine.

D Low-tungsten steel

GENERAL. The application of crank-driven forging machines to production of bolts, nuts, and rivets, as well as to the manufacture of mechanical parts, has encouraged the development of many special machines for which specific information cannot be given. The manufacturers of such machines should be consulted.

PRESS FORGING. Impression dies for production on forging presses are similar in basic design to drop forging dies. Forging steps can be made in separate blocks and fastened in a suitable shoe if desired. Although it has been considered that press forgings should be relatively symmetrical in design for steel and hard alloy forgings, recent advances in press construction and newer techniques produce press forgings not considered desirable a few years ago. Forging presses also find considerable use in cold and hot coining, accurate sizing at low temperature, and restriking.

Percussion presses, or power screw presses, are an intermediate development between the power press and the drop hammer. The slide is driven up and down by a large steep-pitch screw traveling through a fixed nut in the frame to a light flywheel on top. Friction contact of the flywheel rim with a constantly revolving disk on one side drives the slide down at increasing velocity until the die comes in contact with the work and all the energy of the flywheel is absorbed. Then another revolving disk makes contact with the other edge of the wheel and lifts the slide. Foot treadle control, similar to that of a drop hammer, is used. The principal use of the percussion press is on brass and bronze impression die forgings. Common press sizes range up to about 1000 tons forging pressure.

Hydraulic forging presses have followed the forging hammer in development. They were essentially slow-moving machines because of fluid friction and the inertia of long columns of liquids and of accumulators. These characteristics tended to limit their operations to hot forming on parts heavy enough to hold heat over a considerable time and to a limited field of cold operations. Subsequent developments have increased their speed materially by introduction of variable-delivery motorized pumps, gravity fill systems, and foot valve controls. Fast-acting hydraulic presses are adapted to some production metalworking operations and have been used on some impression die forgings. Other operations include hot extrusion of shells and shapes, heavy bending, and flattening. Common sizes range from about 250 tons forging pressure to about 10,000 tons. Special hydraulic forging presses up to 18,000 tons are in operation.

Extruding is limited in its usefulness in so far as hydraulic forging of steel is concerned. It is a major operation in the production of various cross-sectional shapes of lead, tin, zinc, copper, aluminum, etc. Such shapes in the form of rods or bars are made by forcing the metal through an aperture die by high pressure, producing smooth surfaces, free from flaws, to close dimensions, and generally imparting higher physical properties to the subject. Reference 2 contains much detailed information on extrusion of nonferrous metals.

Punches and Dies. Punches must be rigid to maintain concentricity and tough to withstand abrasive action. Chrome-nickel steels generally have the longest life. Since scoring due to abrasion starts at the tip, renewable tough cast-iron tips frequently are used in order to reduce the expense of renewals. Cooling and lubrication are required between piercing operations.

Dies for piercing operations commonly are constructed in the form of a steel jacket completely enclosing a renewable cast-iron liner, bored to suit the outside diameter required of the forging. Such dies have stripper plates to strip the forging from the punch, and the larger sizes are slidably mounted on the lower platen of the press to permit mechanical handling.

The mean average life of punches and die liners for forgings over 6 in. in diameter is approximately 600 forgings. Smaller forgings may result in tool life of double or triple this amount.

Drawing dies are made of the hardest close-grained iron. It is common practice to use 20 degrees as an entrance angle and 12 degrees as the friction angle of the die. (See Fig. 7.)

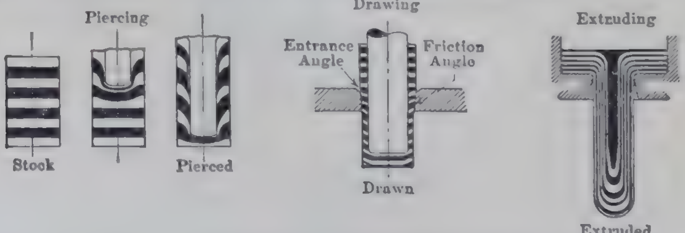

FIG. 7. Plastic flow in hydraulic press operations.

Some dies have a curved entrance. Dies may be mounted in series for multiple-drawing operations. The larger drawn forgings are produced on horizontal presses called draw benches.

Mechanical forging presses, of the eccentric crank type, have extended their activity in the impression die forging field in recent years, their rugged rigidity and high speeds being important factors. Present speeds are from about 85 to 125 strokes a minute for smaller presses to about 45 to 70 strokes a minute for larger presses. Common sizes range from about 750 tons forging pressure to about 6000 tons.

3. IMPRESSION DIES

FUNCTION OF IMPRESSION DIES. The purpose of the impression die is to change the shape of the forging stock, which is normally round, square, or flat in cross section, to the shape and dimensions of the finished forging, at the same time regulating the metal flow to maintain sound structure and unbroken flow lines. Metal, heated to its plastic state, is flowed under forging pressure through a series of forging steps contained in the impression dies. The number of forging steps is dependent on the kind of shape change necessary and the amount of change.

Simple symmetrical parts may be forged directly in the finishing impression (finishing die cavity) without preliminary shaping. The more difficult shapes may require two to ten different steps to produce the part as a finished forging. The most-used preliminary forging step is the *edger*, which serves to proportion the cross-section area along the length by flowing metal from a section being reduced to a section being enlarged. The *fullering step*, or *fuller*, reduces the cross-section area between the ends of the forging stock without appreciable change to the end sections. The *bending step*, or *bender*, forms the length of the forging stock to a shape for the finishing impression. The *blocking* impression, or *semifinishing impression*, shapes metal to an approximation of the final shape. Where possible, all the forging steps, including the finishing impression, are contained in one set of die blocks. Pieces with large surface areas, or large forgings, may necessitate the use of two or more sets of die blocks. When the drop hammer and the forging machine are used to produce a forging, two sets of dies are needed.

FORGING STEPS must be designed to make use of the law of natural metal flow, which states that plastic metal spreads and flows along the path of least resistance. Corners, sidewalls, raises, and thin, rapid-cooling sections are barriers to natural metal flow in varying degrees. Similar to a liquid, metal in plastic state will not drop suddenly to fill a pocket but flows over into the cavity in an arc. Thin sections cool rapidly and become less plastic in ratio to their cooling rate. All factors promoting and restricting movement of plastic metal are considered in design of forging steps. The ultimate aim is to proportion the shape in each step so that the metal in the finishing impression will spread to reach all sidewalls at the same time. Experience in forging die design is important.

DIE BLOCKS. Die blocks are available in a variety of compositions to meet a variety of needs. The more commonly used die blocks are made from chromium-molybdenum or nickel-chromium-molybdenum grain-controlled alloy steels, of which these are typical:

Carbon	Manganese	Chromium	Nickel	Molybdenum
0.50–0.70	0.50–0.90	0.60–1.30	1.00–2.00	....
0.50–0.70	0.60–0.90	0.75–1.00	....	0.15–0.25
0.50–0.70	0.50–0.90	0.50–1.00	1.00–2.00	0.15–0.35
0.50–0.70	0.50–0.80	0.75–1.00	1.50–2.50	0.60–0.90

Die blocks are forged on all six faces—upset to destroy all original directional fibers, an essential factor since the forging forces are exerted in all directions in a die cavity. Die block steel is never permitted to become cold from the time the ingot is cast until final tempering treatment. Blocks are normalized, quenched, and tempered. The blocks are machined and ground on the working surfaces to secure a well-prepared surface for hardness testing. Standard alloy blocks are available in four normal hardnesses for commercial use, the highest of the standard hardnesses being 56 to 60 Scleroscope hardness. Where hardnesses beyond machinable ranges are desired for use on thin light sections, annealed blocks are machined and then hardened and tempered after impression machining. Figure 8 shows a hammer die.

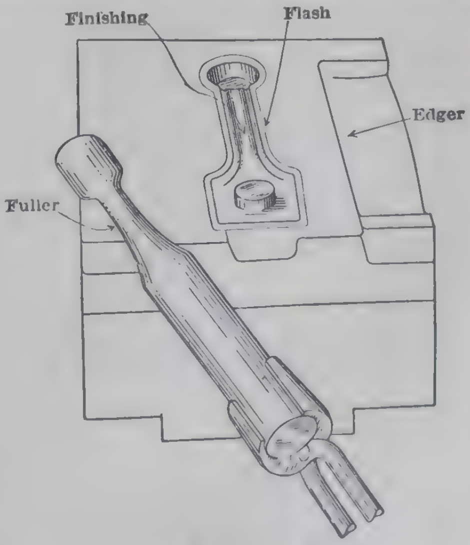

Fig. 8. Hammer die.

IMPRESSION MACHINING and preparation of the rough die blocks for use in the drop hammer, forging machine, or forging press is performed in standard machine tool equipment such as the planer, shaper, drill press, lathe, and in special vertical milling machines known as die sinking machines. Suitable benches are used for final polishing and sizing of the finishing impressions. It is important that the finishing impression be polished to a high degree of smoothness. Blocks are first squared up for impression layout. Drop forging die blocks have shanks cut on by planing or shaping, working surfaces are machined parallel with shanks, and match edges are machined, to assure alignment of cavities. Blocks for machine forging are planed or shaped to fit the machine pockets. Impressions and preliminary forging steps are machined, and impressions are polished to high smoothness.

DIE SETTING or installation of impression dies is important to produce smooth, closely dimensioned die forgings. The final blow struck on a die forging, and producing the exact reproduction from the dies, also is that blow which has the least vertical displacement and hence absorbs the greatest amount of available energy in the least time. It, therefore, is important that in the reproduction of exact forgings, the dies be set so that the displacement load of the final impression is centered under the falling mass. Since die design can only approximate the load distribution, it is necessary that adjustable yet rigid means of fastening dies in the hammer be employed. Figure 9 shows a typical dovetail fastening for dies. Shims are used on the sides of the slot for left to right adjustment, and a series of dowels with graduated offsets provides adjustment from front to back. Forging machine dies and forging press dies are fastened in place by the use of clamps and dogs.

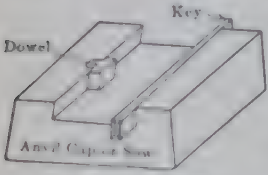

Fig. 9. Die notch.

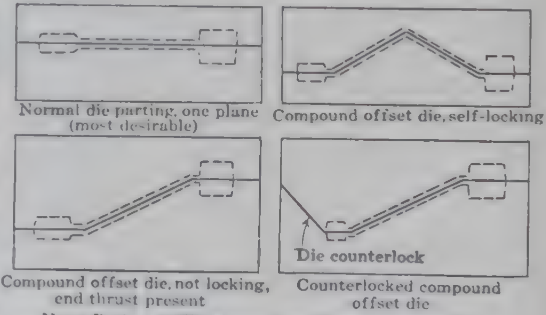
4. DESIGN OF FORGED PARTS

Forging design as applied to impression die forgings is conventional design to completely satisfy the service requirements of a component, incorporating, as far as possible, design in keeping with good production forging practice and subsequent processing. Good original design for a particular type of production method is highly desirable where possible. All impression die forgings have similar basic requirements whereas a particular method of forging production may entail some modifications. The largest volume of impression die forgings are made as drop forgings.

DROP FORGING DESIGN must give first consideration to the die parting plane, since forging draft must be added to all sides vertical to the parting plane. If possible, it is desirable to part the forging with a single horizontal plane with half of the forging in the bottom die and half in the top die. The single horizontal parting plane (normal plane) is possible on a large portion of drop forgings, although it is not possible always to divide the forging evenly between the two dies. Some shapes make it desirable to part in two or more planes. Dies parted in two or more planes are called locked dies. Figure 10 sketches normal and locked die parting planes.



Normal die parting, one plane (most desirable)

Compound offset die, self-locking

Compound offset die, not locking, end thrust present

Counterlocked compound offset die

Note: Broken outline shows drop forging in position.

Fig. 10. Parting planes in drop forging dies.

Forging draft is taper given to all sides vertical to the parting plane of the drop forging to permit easy removal of the forging from the dies. Normal drop forging draft is 7 degrees for all outside surfaces and 10 degrees for all inside surfaces. Thin flat drop forgings may permit small reduction in draft requirements, and drop forgings with high bosses or deep pockets may require an increase in the amount of draft.

Fillets and corner radii connect and blend the several planes in the forging. They should be made as large as the design will permit, particularly on parts containing deep pockets

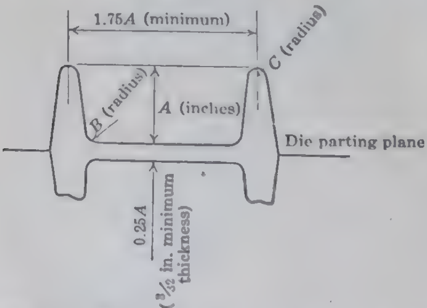


Fig. 11. Thickness, fillet, and corner radius limits. See Table 2.

or high bosses. Sharp corners restrict normal metal movement, increase die wear, and promote defects. Ample radii and fillets permit gradual changes in directional flow of plastic metal. Table 2 and Fig. 11 suggest minimum fillets and radii.

Table 2. Suggested Minimum Fillet and Radii (Fig. 11)

A	3/8	1/2	3/4	1	1 1/4	1 1/2	1 3/4	2	2 1/4	2 1/2	2 3/4	3
B	3/16	1/4	5/16	3/8	1/2	9/16	5/8	5/8	11/16	11/16	3/4	3/4
C	1/32	3/64	1/16	5/64	3/32	7/64	1/8	9/64	5/32	11/64	11/64	3/16

Ribs and Thin Sections. Ribs in forgings restrict metal flow into the narrow die cavity; both ribs and thin sections cool metal quickly, making it less plastic. Maximum possible draft angles and ample radii promote greater forging ease in forging full sections with suitable tolerances.

Bosses and stems are projections extending away from the main body of the drop forging. The addition of draft is dependent on their position with relation to the die parting plane. Vertical bosses and stems usually require addition of draft. Horizontal bosses and stems generally require only end draft. Figure 12 illustrates draft, fillets, pockets, bosses, and radii.

Die shift is a condition in the drop forging where the top die is not in complete alignment with the bottom die, for one of several reasons: improper die alignment, tendency of top die to pull off center, loose die key, or excessive running clearance in hammer ram. A small amount of die shift may be unavoidable in some types of drop forgings.

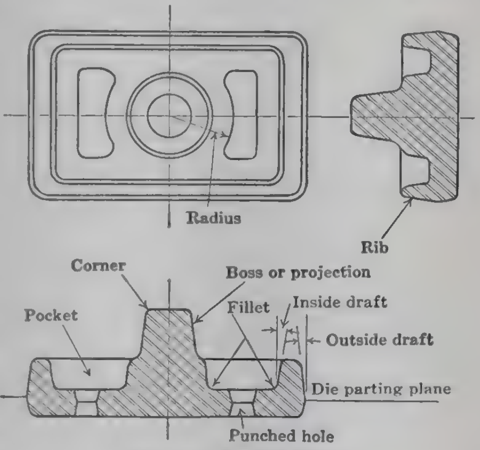

Fig. 12. Forging terms.

TOLERANCES on drop forgings should be to standard commercial practice where use of the part will permit. Drop forging tolerances, as outlined by the Drop Forging Association for drop forgings of 0.1 to 100 lb, are given here.

Tolerances shall be either "Special" or "Regular."

"Special" tolerances are those which are particularly noted in the specifications and may state any or all tolerances in any way as occasion may require. Special tolerances apply only to the particular dimension or thing noted. In all cases where Special tolerances are not specified, Regular tolerances shall apply.

"Regular" tolerances are divided into two divisions—"Commercial Standard" and "Close Standard." "Commercial Standard" tolerances are for general forging practice, but when or where extra close work is desired involving additional expense and care in the production of forgings, "Close Standard" may be specified. "Close Standard" may be specified for one or more of the following classes. When no standard is specified, "Commercial Standard" shall apply.

Classes. Regular tolerances are applicable to the following classes: (1) thickness; (2) width, including (*a*) shrinkage and die wear, (*b*) mismatching, and (*c*) trimmed size; (3) draft angle; (4) quantity; and (5) fillets and corners.

Class 1. Thickness Tolerances (Table 3). Thickness tolerances shall apply to the overall thickness of a forging. When applied to drop hammer forgings, they shall apply to the thickness in a direction perpendicular to the main or fundamental parting plane of the die. When applied to upset forgings, they shall apply to the thickness in a direction parallel to the direction of travel of the ram, but only to such dimensions as are enclosed by and actually formed by the die.

Class 2. Width and Length Tolerances. Width and length tolerances shall be alike and shall apply to the width and/or length of a forging. When applied to drop hammer forgings, they shall apply to the width or length in a direction parallel to the main or fundamental parting plane of the die, but only to such dimensions as are enclosed by and actually formed by the die. When applied to upset forgings, they shall apply to the width or length in a direction perpendicular to the direction of travel of the ram.

Width and length tolerances shall consist of three subdivisions:

Class 2. (*a*) Shrinkage and die wear tolerance.
Class 2. (*b*) Mismatching tolerance.
Class 2. (*c*) Trimmed size tolerance.

Class 2 (*a*). Shrinkage and Die Wear Tolerances. Shrinkage and die wear tolerances shall apply to that part of the forging formed by a single die block only. They shall not apply to any dimension crossing the parting plane. They shall be the sum of the shrinkage tolerances and the die wear toler-

36	.108	.054	51	.107	.054

ances as given in Table 4. The shrinkage tolerances and die wear tolerances shall not be applied separately, but shall only be used as the sum of the two. They shall not be so applied as to include draft or variation thereof.

Class 2 (*b*). Mismatching Tolerance (Table 5). Mismatching is the displacement of a point in that part of a forging formed by one die block of a pair, from its desired position when located from the part of the forging formed in the other die block of the pair. Mismatching does not include any displacement caused by variation in thickness of the forging, but is only the displacement in a plane parallel to the main or fundamental parting plane of the dies.

Mismatching tolerances are independent of, and in addition to, any other tolerances.

Class 2 (*c*). Trimmed Size Tolerances. The trimmed size shall not be greater or less than the limiting sizes at the parting plane imposed by the sum of the draft angle tolerances and the shrinkage and die wear tolerances.

Class 3. Draft Angle Tolerances (Table 6). Draft angle tolerances are the permissible variations from the standard or nominal angle of draft.

Class 5. Fillet and Corner Tolerances. Fillet and corner tolerances apply to all meeting surfaces even though drawings and/or models indicate sharp corners, unless such drawings and/or models

have or indicate (even though actual dimensions are not specified) fillet and/or corner dimensions of larger radii than the following standards, in which case such actual or indicated larger dimensions shall be considered as actually specified and the tolerances shall be "Special Tolerances."

Fillet tolerances apply to inside corners and edges in all cases in which surfaces meet at an angle less than 180 degrees.

Corner tolerances apply to outside corners and edges in all cases in which surfaces meet at an angle greater than 180 degrees.

Where a corner tolerance applies on the meeting of two drafted surfaces, the tolerance shall apply to the narrow end of such meeting and the radius will increase towards the wide end. The total increase in the radius will equal the length of the drafted surface in inches, multiplied by the tangent of the nominal draft angle.

The radii of fillets and corners may be any value not greater than those given in Table 7.

MACHINE FORGING DESIGN permits modification with respect to forging draft, inasmuch as most forging-machine forgings do not require draft. Consideration similar to drop forgings must be given machine forgings with respect to ribs and thin sections. Center holes in machine forgings can be straight and deep. In general, forging machine products are relatively symmetrical in nature.

PRESS FORGING DESIGN in steels and harder alloys is similar to drop forging design. The high-speed forging press is especially adapted for symmetrical parts in large production quantities, with most of such shapes being made with less draft than the drop forging, and some without draft since ejecting devices can be employed. Many shapes that are not symmetrical in themselves can be paired to obtain reasonable symmetry. Some forgings are preshaped by forging rolls or forging hammers and finished forged on the forging press.

Design of press forgings in impression dies on the softer metals such as brasses and bronzes is almost unlimited as to shape, and little consideration need be given draft angles or radii. Such impression die forgings must not contain undercuts. The fact that brass and bronze forging metal can be extruded as well as flowed under pressure permits the making of shapes that are not considered practical in the harder compositions such as steel. The older types of press-forging equipment have draft requirements from 1 to 3 degrees, and the newer equipment can produce brass and bronze forgings without draft. The working pressures and temperatures are less severe on the softer nonferrous metals, and dimensional tolerances can be held fairly close. Some of the high-strength forging bronzes do not work quite as readily as the forging brasses and may impose moderate limitations on difficult designs.

SUBSEQUENT PROCESSING OPERATIONS. Forgings made by the use of impression dies usually require one or more steps in the forging plant before they are ready for further processing in the heat treat or machine shop. All drop forgings and most press forgings are trimmed to remove excess metal in the form of flash. Trimming is done cold or hot in mechanical or hydraulic power presses. Other press operations may be forming, coining, restriking, sizing, straightening, and planishing. Shot blasting, pickling, or tumbling are routine operations to remove forging scale. Normalizing, annealing, quenching, and tempering may be treatment requirements.

Allowance for Machining. The amount of metal added to finish machined surfaces on the impression die forging is dependent on the size and shape of the part, metal composition, and machining operations. Average impression die forgings which require normal machining operations such as turning, boring, shaping, or milling should allow a minimum of $^{1}/_{32}$ in. of metal on each surface to be machined on small forgings weighing a pound or under, and $^{1}/_{16}$ in. is desirable where it can be permitted. Slight variations in size, small scale pits, surface blemishes, and die shift may cause surface or width variations from a few thousandths of an inch to $^{1}/_{32}$ in. Average forgings from 1 to 20 lb should allow a minimum of $^{1}/_{16}$ in. for each machined surface; forgings from 20 to 50 lb, a minimum of $^{3}/_{32}$ in; forgings from 50 to 100 lb., a minimum of $^{1}/_{8}$ in.; and forgings over 100 lb, a minimum of $^{1}/_{4}$ in. Modern heavy-duty machine tools involve less difficulty and expense in the removal of a little extra surface metal than are entailed in the design of jigs and fixtures for exact positioning of the forging.

Smith forgings require a greater allowance for machining than is necessary for impression die forgings. Weldless forged smith rings up to 8 in. OD require $^{3}/_{8}$ in. added to OD and thickness and $^{3}/_{8}$ in. deducted from ID. Rings of 8 in. OD to 15 in. add $^{1}/_{2}$ in. to OD and thickness and deduct $^{1}/_{2}$ in. from ID. Rings 18 in. OD to 30 in. add $^{5}/_{8}$ in. to OD and thickness and deduct $^{5}/_{8}$ in. from ID. Rings 30 in. OD to 50 in. add 1 in. to OD and thickness and deduct 1 in. from ID. General smith shapes require a minimum of $^{1}/_{4}$ in. added for each surface to be machined.

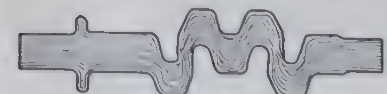
Gear blank forging



Crankshaft forging

Fig. 13. Flow lines in forgings.

Machining heat-treated forgings is increasing in use with newer steels, machine tools, and improved techniques. Any greater difficulty in machining the forging in the heat-treated state is compensated for by minimizing or elimination of problems in warpage, size changes, scaled or discolored surfaces, spoiled tolerances, and heat treating cracks due to sharp machined corners.

FLOW LINES. Flow lines, generally known as *grain flow* or *fiber structure*, are present in wrought metals, the result of mechanical working given to the original cast ingots. The minute impurities, inclusions, and oxides are lengthened in the direction of working by mill rolling or hammer forging and develop a grain in the wrought metal somewhat like the grain in fine hard wood. The importance of flow-line position or direction in the forging is the great increase in resistance strength to dynamic stresses of impact, shock, vibration, and fatigue by correct positioning.

Results of tensile tests and Izod notch impact tests on standard specimens indicate that although there is little or no practical change in tensile strength and yield strength on specimens taken in the longitudinal and transverse directions, the percentage of elongation and the reduction in area drop sharply for specimens taken in the transverse direction. Values in foot-pounds obtained from notch impact specimens in the longitudinal direction were nearly three times the values obtained from specimens in the transverse direction. Interpreted broadly, flow-line position is of little importance in a component where stresses are static, occasional, and not severe. Flow-line position is important on all parts that encounter variable and dynamic stresses, such as variable and reversible loads, intermittent shock, impact, vibration, wear, and fatigue. Positioning of flow lines is especially important in aircraft forgings where maximum strength with minimum weight is mandatory and where "unpredictable stresses" can be encountered. Figure 13 illustrates flow lines in forgings.

STAMPING PROCESSES

By Lester V. Colwell

The purpose of this chapter is to aid the mechanical or process engineer in making decisions about the selection of material, process, and the equipment for metal stamping. These selections are necessarily preliminary to the final design of a component part or product. A product must be designed to meet service requirements, but the cost of production may be unnecessarily high unless some consideration is given to the limitations of the methods of production before the design of the product is frozen. In addition, slight alteration in design of the product often makes it possible to use a process with much lower production costs. Thus it is the purpose of this chapter to present the production advantages offered by the many operations that can be performed by metal stamping, and in particular to emphasize the limitations of those operations.

In general if a part can be made as a metal stamping it can be produced in large quantities at a lower cost than by any other process. A wide range of sizes and quantities can be produced economically. A very broad range of properties is available in the metal ranging from low strength nonferrous alloys to high-strength stainless steels. Any metal which can be prefabricated as sheet or strip can be processed further by at least some of the metal stamping operations.

The steps in planning production by stamping generally are taken in this sequence: (1) Preliminary design of the component. (2) Selection of material for the component. (3) Selection of stamping operations. (4) Grouping of stamping operations. (5) Final design of component. (6) Selection of presses and auxiliaries. (7) Selection of heat-treating processes and equipment. (8) Selection of cleaning processes and equipment. (9) Selection of finishing processes and equipment. (10) Design of stamping dies.

5. ANALYSIS OF STAMPING OPERATIONS

The limitations of the stamping process are not very well established quantitatively because of the apparent complexity of the causes. Consequently they are not well understood, and often are misinterpreted. There is a considerable quantity of published as well as unpublished data on metal stamping and die design. Some of these data are empirical, but the vast majority are completely arbitrary. Therefore a general discussion of the theoretical aspects should aid in simplifying as well as minimizing errors in applying them.

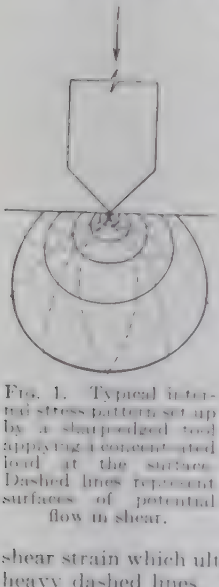

FIG. 1. Typical internal stress pattern set up by a sharp-edged tool applying a concentrated load at the surface. Dashed lines represent surfaces of potential flow in shear.

All metal stamping operations can be grouped into either of two classifications, *cutting* and *forming*. A few operations, such as burring and lancing apparently belong to both classes, but actually the cutting phase of the operation either precedes or follows the forming phase so that two or more distinct operations are performed in sequence by the same tool.

CUTTING operations are distinguished by the obvious fact that the material is completely sheared or cut by stressing it beyond its ultimate strength. These operations seldom give rise to serious operating difficulties. Therefore an understanding of a relatively few characteristics of the cutting process makes it possible to apply all the operations of this class with assurance of success.

Figure 1 gives an indication of the mechanism of metal cutting or shearing. It illustrates the stress set up in metal by a sharp-edged tool like a cold chisel. Each of the solid curved lines represents a region of uniform compression or principal stress. The shear stress, which is the first to reach yield condition, is a maximum on surfaces at 45 degrees to the surfaces of uniform compression. The dashed lines represent possible surfaces of propagation of shear strain which ultimately become surfaces of rupture such as the two designated by the heavy dashed lines. The stress obviously is greatest at the edge of the tool, and shearing rupture begins at this point. Shearing may begin several times in different directions before yielding, and consequent relaxation of stress finally permits the shape of the chisel or cutting edge to impose a fixed pattern of stress, thus propagating rupture to appreciable depth below the surface.

Figure 2 shows a typical flat-end tool like a piercing punch being forced into the surface of the metal. The stress pattern is similar to that shown in Fig. 1 but it is influenced by the shape of the punch and the amount of penetration of the punch in the metal before the shearing is completed. It is apparent that the cut surface is not cut in the same sense as a turned or a milled surface. The cut surface is created by a true rupture in shear propagated ahead of the punch. Therefore a hole pierced under ideal conditions increases in cross section as it approaches the bottom of the sheet.

Figure 3 exaggerates the conditions of shearing in a hypothetical blanking operation wherein the relatively thin sheet metal bends elastically prior to the completion of the shearing and exerts an additional influence on the direction of propagation of the sheared surface.

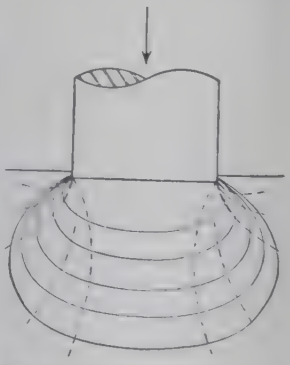

FIG. 2. The internal stress pattern set up by a punch similar to those used for cutting sheet metal.

It has been claimed that the shear surfaces start almost simultaneously from the upper and lower cutting edges, and that ideal clearance between punch and die opening will permit the two sheared surfaces to meet in a common surface near the middle of the sheet. This is highly improbable since the necessary conditions are perfect homogeneity of the sheet and identical stress conditions at both cutting edges. This latter condition is possible only with identically sharp cutting edges.

At low cutting speeds it is probable that cutting begins at the sharpest cutting edge and propagates very rapidly through the sheet almost to the opposite cutting edge before any appreciable cutting takes place at that point. At higher cutting speeds the inertia of the sheet causes a greater force on the cutting edge in motion relative to the sheet. Thus it can be expected that cutting will be initiated by the moving cutting edge in dies which have been recently reground or in dies where the rate of dulling is the same for both cutting edges.

The nature of cutting or shearing in stamping dies is such that the best job of cutting still produces a cut surface not perpendicular to the surfaces of the sheet, but inclined from one cutting edge to the opposite cutting edge. This idealized condition is illustrated in Fig. 3.

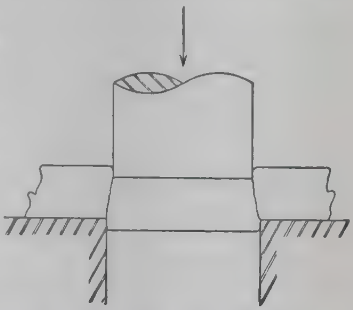

FIG. 3. With ideal conditions the sheet metal is cut by the propagation of shear surface angularly from the sharp cutting edges until the surfaces meet in a continuous surface. Shearing is completed before the punch penetrates the entire thickness of the sheet metal. The degree of angularity is a function of the sheet metal properties and determines the proper clearance between punch and die for a clean cut.

In practice it is difficult and uneconomical to maintain perfectly sharp cutting edges, uniform clearance between the cutting edges, and uniform properties of the sheet metal. Dull cutting edges cause less stress concentration than sharp cutting edges; consequently, greater penetration is required before shearing is effected. Greater penetration inclines the sheared surface at a greater angle from the line of motion of the punch, thus creating the effect of too little clearance. Soft ductile metals require greater penetration to effect shearing than the harder, less ductile metals. Therefore the proper clearance between cutting edges increases with increase in ductility or per cent elongation of the sheet metal. Figure 4*a* illustrates the proper clearance condition for both hard and soft metals.

Figure 4*b* shows the effect of dull cutting edges and too little clearance. Too little clearance or dull cutting edges usually cause a burr to be left on the die side of the stock surrounding the punch. This burr may be accompanied by a slight undercut at the same point when cutting relatively thick stock. The same defects, i.e., burr and undercut, will be present on the punch side of the material cut out of the stock. Too much clearance gives opposite results as shown in Fig. 4*c*. The burr and undercut occur near the punch side of the stock surrounding the punch and near the die side of the material cut out of the stock. It will be noted in Figs. 4*b* and 4*c* that the burr created by too little clearance increases the effective thickness of the material whereas the burr created by too much clearance is turned away from the surface of the stock and does not affect the thickness of either the part or the stock from which it was cut. Consequently, too little clearance is more serious than too much clearance where the proper clearance cannot be maintained.

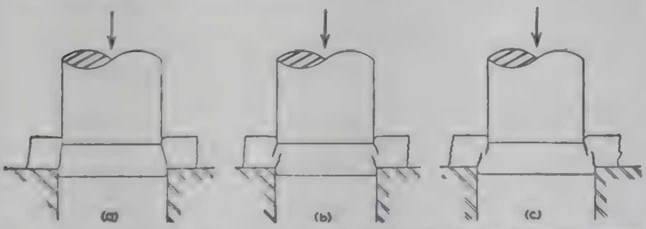

FIG. 4. (*a*) Ideal conditions produce a clean cut; (*b*) too little clearance, dull cutting edges, or increased ductility cause condition shown; (*c*) too much clearance or decreased ductility cause this condition.

The most common occurrence is nonuniform clearance combined with directional differences in the ductility of sheet metal. The most effective ways to control the frequency and size of burrs are (1) Use only rigid, accurately built dies. (2) Set up and maintain an adequate regrinding schedule. (3) Maintain uniformity of stock through acceptance inspection.

These are rules for maintaining satisfactory production, once it has been set up. However, the foregoing discussion of the mechanism of the cutting operations is important to the selection of stamping as a means of processing a part. It is obvious that even ideal cutting conditions will not maintain dimensions within limits as close as is possible with machining operations. The tolerance on the size and shape of a pierced hole or of a sheared blank need not exceed the proper total clearance.

The proper clearance is determined by the thickness, strength, and ductility of the sheet metal. It is usually expressed as a percentage of the metal thickness varying from 2 to as much as 15%. The ductile metals, which are usually low in hardness, require considerable clearance and relatively large tolerances. Dead soft copper, 2-SO aluminum, and Armco iron are typical metals possessing high ductility. An increase in hardness or a decrease in strength accompanied by a decrease in ductility reduces the penetration and consequently the clearance for a clean fracture. High silicon steel which requires as little as 2 to 3% clearance is typical of the other extreme. The tolerances on relative location of component details such as center distances are dependent on the type of die construction. This problem is discussed in Article 7 under the heading Characteristics and Applications of Dies.

The essential characteristics of the cutting group of stamping operations impose limitations summarized as follows:

1. The selection of ductile metals such as are required for forming operations requires minimum component tolerances of 10 to 15% of stock thickness for the size and shape of sheared details.
2. Smaller tolerances than those designated in (1) above can be obtained on parts stamped from ductile metals by subsequent machining operations, such as shaving, broaching, boring, and reaming.
3. Relatively small tolerances can be maintained down to about 0.003 in. by the selection of a material too hard for forming.
4. Smaller tolerances can be maintained by selecting sheet or strip which has been rolled in two directions rather than continuous strip or coil stock which can be rolled in only one direction. A straight-line cut, parallel to the direction of rolling, requires less clearance than a similar cut across the direction of rolling.
5. Tolerances on location of detail cannot be expected to be smaller than those for size and shape and often must be larger when simple, progressive, or transfer dies are used.

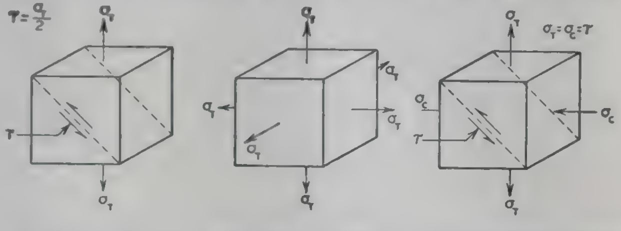
FORMING operations are used to produce a desired shape from the sheet metal. This is accomplished by straining it beyond the yield point so that it will take a permanent set and retain the new shape. The operation must be controlled to such an extent that all regions of the part which have assumed a new shape will have been stressed at least beyond the yield point, but not beyond the ultimate strength where rupture would take place. It is usually difficult to confine the stresses to a sufficiently small range within these critical stresses. Most operating difficulties stem from stresses too close to either the yield point or the ultimate strength.

Most of the operations in the forming group can be classified in one of two subgroups based on the predominant type of stress set up during the operation. One subgroup is distinguished by the fact that the metal flow produced by the operation sets up both compressive stresses and tensile stresses. The other subgroup is characterized by a predominance of tensile stresses. The latter are frequently called stretching operations. Those operations which set up both compression and tension usually will permit more drastic changes in the shape of the formed part.

The group of forming operations which involves both compressive and tensile stresses of considerable magnitude can be further subdivided on the basis of the type of metal flow. One class of operations, of which conventional drawing is typical, produces the change in shape with no substantial change in the thickness of the sheet metal. Consequently, the area of the part remains almost constant during several stages of processing. In the other class of operations, of which ironing and swaging are typical, the change in shape and size is accomplished primarily through an increase or a decrease in the thickness of the metal. The metal flow is much more severe than in other forming operations.

The degree of difficulty in producing a part by forming is determined largely by the stress pattern, the influence of work hardening, the speed of metal flow, the grain size of the metal, and the friction between the part and the elements of the die. A satisfactory part has good finish, holds its shape against residual stresses, and obviously has not been torn or ruptured during forming. The greatest ease of metal flow occurs when the principal stresses are both tension and compression of equal magnitude, and well beyond the elastic limit but safely below the ultimate strength. Metals differ greatly in their capacity for and rate of work hardening. Obviously a metal with low work-hardening capacity and a high rate of work hardening can be deformed relatively little before the stresses exceed the ultimate strength and the part is spoiled by tearing.

Metals show considerable differences in sensitivity to forming speed. The factors influencing the sensitivity to speed are not completely understood, and considerable research may be necessary before a working knowledge of all variables is obtained. However, it is significant that the degree of success in forming sheet metal may depend on the magnitude of the velocity and the sensitivity of the metals to changes of velocity. The grain size of the metal influences both the ultimate extent of forming and the surface finish. The most desired grain size is often a compromise where both finish and metal flow are critical. Lubrication is especially important in the so-called stretching group of operations. Good lubrication will reduce the friction between the work and the die elements. This reduction of friction will reduce stresses and prevent seizure or welding of the work to the die. A good lubricant is frequently the difference between uninterrupted production on the one hand, and scored or torn parts and short die life.



(a) SIMPLE TENSION (b) TRIPLE TENSION (c) TWO DIMENSIONAL SHEAR

FIG. 5. Basic theoretical stress conditions which can be approached in stamping operations.

Stress Conditions. All metal flow is ultimately reduced to relative movement between adjacent parallel planes and is known as shear; the associated stress is known as shear stress. No permanent set or change in shape can take place unless the shear stress has passed the yield point. However, the loads or motions applied to a metal in an attempt to form it give rise directly to tensile or compressive stresses. Therefore, it is well to review the relationship of the shear stresses to tension and compression. Figure 5 illustrates three basic stress conditions. In simple tension, the maximum shear occurs on a surface at 45 degrees to the direction of the applied external load representing tension (Fig. 5*a*). It can be demonstrated mathematically that the shear stress in pounds per square inch is equal to one-half the tensile stress expressed in the same units. Consequently, the tensile stress required to cause yielding and permanent set is twice the yield point in shear.

If tension is applied equally in all three directions, the net result is no shear. This condition is shown in Fig. 5*b*. Since all metal flow is in a shearing direction, there can be no flow in this case until the ultimate strength is reached, at which condition the metal will rupture. This idealized stress condition has been verified experimentally. The same result, i.e., no shear stress, is obtained if the applied stress is uniform compression in all three directions. Obviously this type of stress pattern should be avoided in metal-forming operations.

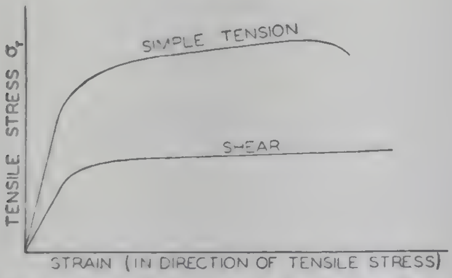


FIG. 6. Forming operations can be more extensive or severe when the punch motion produces two dimensional shear instead of simple tension since metal flow takes place at a lower tensile stress.

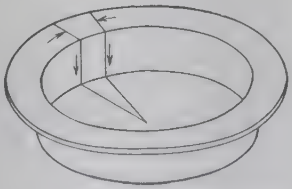

FIG. 7. In conventional drawing of a cup the applied force causes elastic tensile stresses longitudinally in the side wall and radially in the flange; this is resisted by circumferential compressive stresses in the flange which must yield and flow for the drawing to proceed.

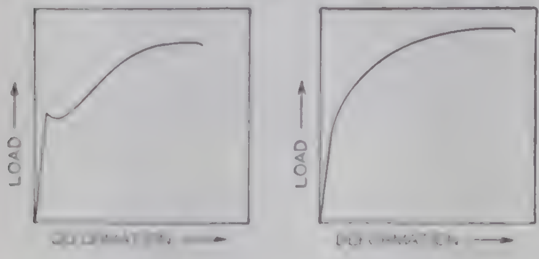
Figure 5*c* shows a third basic stress pattern in which one principal or applied stress is tension whereas the other is compression. The shear stress in this case is equal to one-half the sum of the principal stresses. The shear stress will be equal to the tension and compression when these stresses are equal to each other. This represents an ideal in that metal forming can be accomplished with a minimum of applied force when the induced tension and compression are equal. Figure 6 shows load-deflection diagrams for simple tension and two-dimensional shear wherein the tensile and the compressive stresses are equal.

The advantages of a stress pattern including both tension and compression are demonstrated clearly.

Figure 7 shows the type of metal flow which takes place in conventional drawing. It will be noted that the metal is pulled toward the center of the part by a tensile load or stress. As the metal moves toward the center, however, it must become shorter in a circumferential direction, giving rise to tensile stresses in a radial direction and compressive stresses in a circumferential direction. The load applied by the punch is relatively low compared with the stretching group of operations, where tension is the only significant stress produced by the punch.



(a) (b)

Fig. 8. (a) Typical load-deformation curve for annealed low-carbon steel; (b) slightly cold-worked low-carbon steel showing absence of yield point elongation.

Stress-strain Characteristics. It has been pointed out that sheet metal possessing a high rate of work hardening and a low capacity of work hardening is not suitable for forming operations. Nevertheless it is true that work hardening has some beneficial effects on the surface finish of the formed parts. A rather common defect in the surface of the formed sheet metal parts is the presence of so-called stretcher strains. In industry this condition is referred to variously as stretcher strains, alligator skin, or orange peel; scientific references usually designate stretcher strains as Lüder's lines, the Piobert effect, Hartmann lines, etc. These stretcher strains are a manifestation of incomplete yield point elongation, which can occur in any metal possessing a load-deformation curve similar to that shown in Fig. 8*a* for an annealed low-carbon steel.

If the steel is even slightly cold worked, the load-deformation curve is similar to that shown in Fig. 8*b*, where there is no yield point elongation. A sheet metal possessing this property, i.e., no yield point elongation, will not produce stretcher strains which might mar the surface of the formed part. The necessary amount of cold working or work hardening to produce this desirable effect can be obtained by a small amount of reduction in thickness of the sheet metal during the cold-rolling process; this is sometimes known as a temper roll or temper pass. Figure 9 contains a series of stress-strain curves illustrating the effect of progressively increasing amounts of cold reduction, and consequently an increasing amount of cold working. It will be noted that the stress-strain curve for the annealed sheet of mild steel possesses distinct yield point elongation, whereas as little as 5% reduction in thickness by cold rolling is sufficient to remove the undesirable yield point elongation which produces stretcher strains. It will also be noted that any further work hardening succeeds only in reducing the amount of elongation required to produce rupture of the material. Therefore, in summary, a small amount of work hardening obtained by cold rolling will aid in producing desirable surface finish of the part, although a greater amount of work hardening simply reduces the extent to which the shape of the part can be changed during processing.

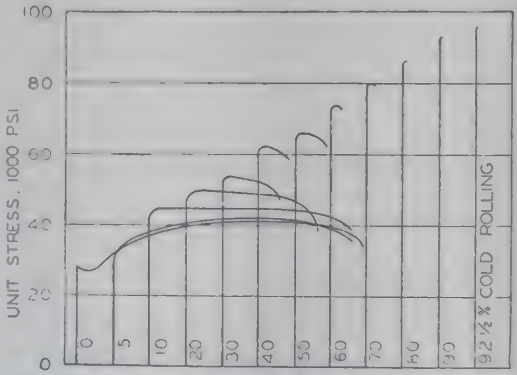


Fig. 9. Effect of cold reduction on the shape of the stress-strain curve of mild steel sheets. (Hayes and Burns, *Trans. Am. Soc. Metals*, Vol. 25, 1937, p. 129)

The velocity at which a metal is made to flow during forming operations also has a very influential effect. There is a need, however, for considerable more research on this problem. The research which has been carried out, although inadequate, has emphasized two things: first, there is a considerable difference between metals as to their sensitivity to velocity; and second, increases in the velocity of straining metals exert a very large influence on physical properties. Figures 10 to 13, inclusive, show typical results of a study made by Winlock and Leiter.* This study involved tests of five samples of a low-carbon steel representing grain sizes at 100 magnification of 20 grains per sq. in. to 200 grains per sq. in. The tests were conducted with standard tensile test specimens for sheet metal with speeds of load applications varying from as low as 0.0046 to as high as 10.1 in. per min.

* J. Winlock and R. W. E. Leiter, Some factors affecting the plastic deformation of sheet and strip steel and their relation to the deep drawing process, *Trans. Am. Soc. Metals*, Vol. 25, 1937, p. 163.

It will be noted in Fig. 10 that there is a substantial increase both in the yield point and in the yield point elongation. A similar influence of speed or velocity is shown in Fig. 11, which gives the results obtained from the 200-grain steel. Figure 12 summarizes the influence of grain size on yield point elongation at four different strain velocities.

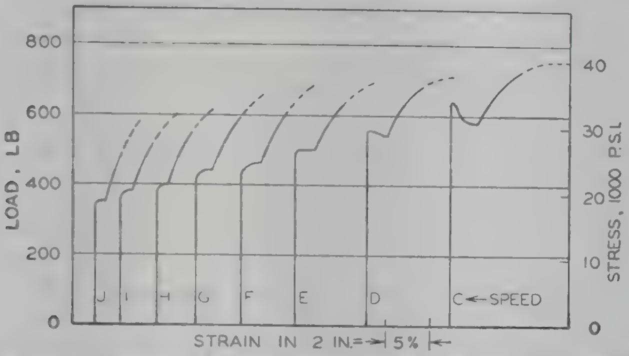

Fig. 10. Load-deformation curves at different constant rates of deformation; $J = 0.0046$ in. per min, $C = 10.1$ in. per min. Low-carbon steel with 0.05% carbon; grain size equals 20 grains per sq in. at 100×. (Winlock and Leiter, *Trans. Am. Soc. Metals*, Vol. 25, 1937, p. 163)

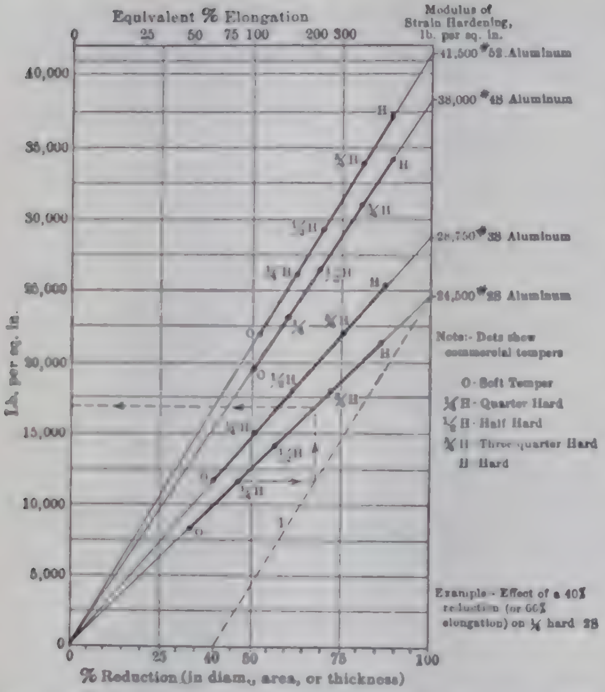

FIG. 14. Plastic range chart for four grades of aluminum at room temperature.

Figure 13 summarizes the influence of testing speed on yield point elongation for both the 20- and 200-grain steels. These results seem to indicate that fine grain steels are more desirable for forming operations, and that the operations should be performed at relatively high velocity. It must be recalled, however, that the strain velocities represented in these tests are substantially below those in general use in industry. Consequently, there remains a broad range of strain velocities which need to be investigated as to influence on physical properties, and relation to composition and microstructure of the metal.

If the factors which influence the formability of metals are summarized, it must be concluded for the present that insufficient information is available on the influence of the speed of forming and the grain size. The composition, microstructure, and grain size of the metals to be used for forming operations are subject to constant revision and improvement, and can be specified most reliably by the metals suppliers. A more useful type of information is available on the effect of strain hardening, as exemplified in Figs. 14 and 15. Figure 14 permits adding the effect of a series of cold-working operations, judging the need for annealing, and finding the yield point or resistance developed in an operation for determining equipment required. The plastic range, or useful working range for each metal, is indicated by heavy lines; and the standard aluminum tempers (listed beside Fig. 14) are indicated in order by dots. A similar procedure can be followed for the information shown in Fig. 15. Additional curves of the type shown in Figs. 14 and 15 can be prepared for other metals from information given in Table 1.

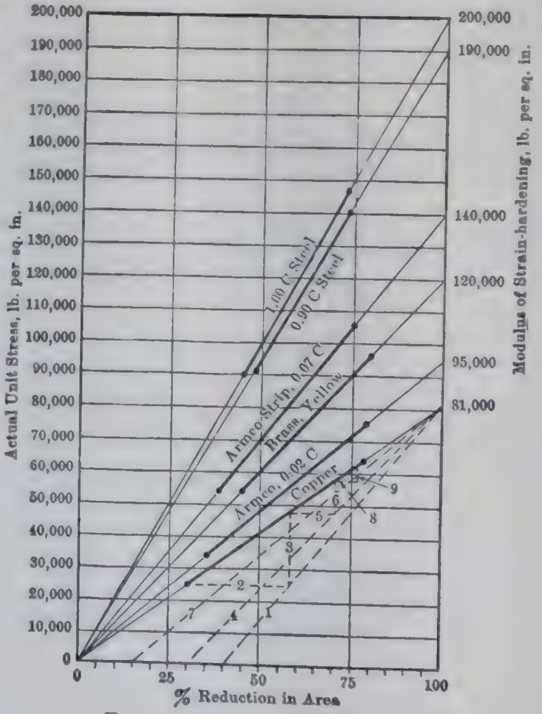

FIG. 15. Strain-hardening curves.

EXAMPLE 1. A reduction of 40% is to be made on 2S aluminum 1/4H. On Fig. 14, first draw a line from the modulus of strain hardening of 2S aluminum (24,500), to 40% on the base line, then a line horizontally from the initial state (1/4H) across to line 1. Then draw a line vertically upward to a point representing completion of the work on the plastic curve. A horizontal line drawn from this point back to the unit stress line shows about 16,500 psi yield point reduction.

EXAMPLE 2. Determine the cumulative

strain-hardening effect of a series of operations on copper, and check approximately whether or not an annealing operation is required. It is assumed that copper is received in the soft temper or commercially annealed state and that the operations to be performed involve successive reductions of 40, 30 and 50%. (See Fig. 15.) The construction lines, numbered in order, indicate successive yield points as follows: Before the first operation, about 25,000 psi; after the first operation, about 42,000 psi; after the second operation, about 51,000 psi; after the third operation, about 62,000 psi. The final point is still within the plastic range of the material so that an annealing operation has not yet been required. It is obvious, however, that the material is now severely strain hardened and must be annealed before any further working is possible.

Annealing and lubrication are important auxiliary functions in the processing of sheet metal even though they are not closely integrated with the theory of metal cutting and forming. Heat-treating practice and equipment are metallurgical subjects and are not discussed in this chapter. It appears desirable, however, to call attention to one heat-treating problem which is the most common source of difficulty with sheet metals. Most metals possess the property of abnormal grain growth at particular combinations of stress-relieving temperature and amount of prior work hardening. Parts formed from sheet metal are usually strained different amounts in the various regions of the part. Thus, if a partially formed part is stress relieved at a particular temperature, it may contain a region in the form of a band or ring within which the grains have grown abnormally. This region will be much weaker than the other regions with normal grain size, and the part may be ruptured at this point in subsequent forming operations. The temperature at which abnormal grain growth occurs for a particular amount of strain hardening is known as the germination temperature. In order to eliminate abnormal grain growth during the stress-relieving or so-called annealing operations, it is necessary to heat very rapidly to a temperature substantially above all the germination temperatures peculiar to any one group of metal-forming operations. This is a metallurgical problem and must be solved experimentally during the setting up of operations.

Lubricants. Table 2 gives summary recommendations of lubricants for use in metal-forming operations. The recommendations made are typical of broad general use in industry. The so-called lubricating materials included in Table 2 are segregated both as to the metals for which they are recommended and the relative severity of forming designated as mild, medium, or severe. All lubricants should be avoided for metal-forming

Table 2. Lubricant Recommendations

STEEL

Mild

Most automobile body forming and shallow draws on low-carbon steel.

1. Mineral oil of medium-heavy to heavy viscosity.
2. Soap solutions (0.03 to 2.0%, high titer soap).
3. Fat, fatty oil, or fatty and mineral-oil emulsions in soap-base emulsions.
4. Lard oil or other fatty oil blends (10 to 30% fatty oil).

Medium

Deep draws on low-carbon sheet steel and drawing wire of low-carbon steel.

1. Fat or oil in soap-base emulsions containing finely divided fillers such as whiting or lithopone.
2. Fat or oil in soap-base emulsions containing sulfurized oils.
3. Fat or oil in soap-base emulsions with fillers and sulfurized oils.
4. Dissimilar metals deposited on steel plus emulsion lubricant or soap solution.
5. Rust or phosphate deposits plus emulsion lubricants or soap solution.
6. Dried soap film.

Severe

Wire drawing medium- to high-carbon steel, seamless-tube drawing, and cartridge-case drawing.

1. Dried soap or wax film, with light rust, phosphate, or dissimilar metal coatings.
2. Sulfide or phosphate coatings plus emulsions with finely divided fillers and sometimes sulfurized oils.
3. Emulsion lubricants containing flowers of sulfur as combination filler and sulfide former.
4. Oil-base sulfurized blends containing finely divided fillers.

STAINLESS STEEL

Mild

1. Corn oil or castor oil.
2. Castor oil plus emulsified soap.
3. Waxed or oiled paper.

Medium

1. Powdered graphite, suspension dried on work before operation (to be removed before annealing).
2. Filler-bearing emulsion lubricant at heavy concentration.
3. Solid wax films.

Severe

1. Lithopone and boiled linseed oil.
2. White lead and linseed oil to a consistency of 600W oil.

Table 2. Lubricant Recommendations—*Continued*

BRASS

Mild

1. Soap solution (0.03 to 2% high titer soap).
2. Fat or oil emulsions with soap emulsifier.
3. Lard-oil blends (10 to 20% lard oil in mineral oil).

Medium

1. Soap solution. Soap should be high titer (39 to 42%), fatty acids and free alkali should be less than 0.07%. Solution should be low concentration (0.3 to 1.0%), and lubricant should contact work at least 30 sec.
2. Fairly rich fat or fatty-oil emulsions with soap emulsifiers. Free fatty acid in the paste base, diluted with 8 parts water, should be at least 2%.
3. Lard-oil blends (25 to 100% lard oil in mineral oil). Free fatty-acid content 1.5 to 5%. Addition of about 1% melted tallow, 0.25% stearic acid to 1 to 2% soap solution is desirable for medium to severe draws.

Severe

1. Soap solution of 0.3 to 1% or one of 1 to 2%, containing 1 to 2% tallow or 0.25% stearic acid. Lubricant and work should be in contact longer than with less-severe draws.
2. Rich lard-oil blends (75 to 100%).
3. Dried soap properly added.

In most instances, brass recommendations apply to copper, although copper welds more rapidly and requires more efficient lubrication than brass.

MAGNESIUM

Mild

1. Graphite (usually colloidal) in mineral oil, high flash point.
2. Beeswax or paraffin and tallow.

Medium

Flake or colloidal graphite in a volatile solvent such as carbon tetrachloride, naphtha or alcohol spread on the work and solvent-evaporated. Add 20% graphite in tallow on the die.

ALUMINUM

Mild

1. Mineral oil, increasing in viscosity as severity of operation increases.
2. Fatty oil blends in mineral oil (10 to 20% fatty oil) or petroleum jelly.

Medium

1. Tallow and paraffin
2. Sulfurized fatty-oil blends (10 to 15%), preferably enriched with 10% fatty oil.

Severe

1. Dried soap film or wax films.
2. Mineral-oil or fatty-oil blends or sulfurized-oil blends, plus finely divided fillers.
3. Fat emulsions in soap water plus finely divided fillers.

operations wherever possible, since they necessitate relatively expensive cleaning operations.

In some instances, where high production continues for an extended period of time, it may prove desirable to reduce friction between the sheet metal and the forming die elements either by chromium-plating the die elements or by plating the sheet metal with tin or copper, particularly where the sheet metal is to be steel. The latter method is particularly useful where soldering or brazing operations are to be employed in fabricating several components into a complete product. The use of sintered carbide for die elements not only reduces friction between dies and sheet metal but also greatly extends the life of the die. The use of sintered carbide for small and medium-sized dies is increasing very rapidly as a result of the development of much more suitable grades of carbides for this purpose.

6. APPLICATIONS AND LIMITATIONS

The following discussion concerns the applications and limitations of most of the metal stamping operations. Because the nomenclature has not been standardized and there are regional differences in the names applied to different operations, an attempt is made either to define or to describe the operations in each instance. The cutting operations used most frequently are discussed first; the forming operations are arranged in a sequence representing increasing difficulty or severity of metal flow.

BLANKING is the act of cutting out a piece of metal of the desired shape and size for the final part (Fig 16). It is most frequently the first stamping operation and is usually followed by cutting or forming operations or both. When blanking is to be followed by cutting operations only, the blank may be cut to the exact final shape and size of the part. When forming operations are to be performed, the shape and size of the blank must be such as to provide some excess of stock in the blank to allow for unpredictable variations of metal flow. The name blanking is sometimes applied somewhat erroneously to the cutting out or removal of a partially completed or even a completed part being processed in a progressive die; the usage is correct to the extent that the operation does establish the perimeter or outline of the part. Blanking is limited only by the ability of the cutting tools to withstand the forces and by ability to machine the punches and dies for complex shapes. With complex shapes it is often advisable to simplify the blanking operation by splitting it up into several punching, slitting, and notching operations. It is usually uneconomical to attempt to maintain a tolerance on the size of a blanked part closer than 0.003 in., and it is often necessary to permit variations as great as 15% of the stock thickness for the softer more ductile metals.

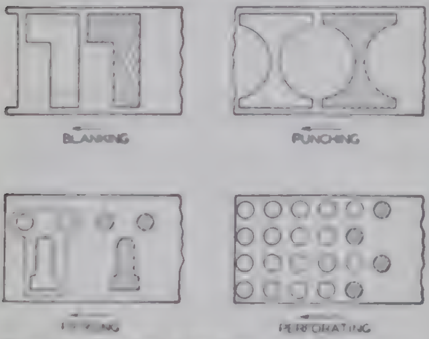

Fig. 16. Typical blanking, punching, piercing, and perforating operations performed in a progressive die.

PUNCHING could be defined as partial blanking since it is often used in progressive dies to cut a major portion of the perimeter of the blank, leaving a small connection with the stock for the purpose of transferring the part between work stages. Like blanking, punching involves a closed cut, i.e., the cutting edge extends entirely around the perimeter of the punch. The edges cut by punching operations seldom constitute any portion of the stamped part since it is used prior to forming operations which require trimming for the purpose of creating the desired perimeter of the part. Therefore, punching imposes no limitations on the design of the stamped part, and the use of the punching operation is limited only by ability to machine and harden the punch and die details.

PIERCING is the hole-cutting operation of the stamping process. It is used in all types of stamping dies for cutting holes of any size and shape for which the punch and die can be machined. The minimum cross-sectional dimension of any hole to be pierced should be at least equal to, and preferably greater than, the thickness of the stock. Figure 16 shows a typical application of a piercing operation in which two round and one irregular hole are pierced in a progressive die prior to the final blanking or cutting out of the finished part.

PERFORATING can be defined as multiple piercing. It is used to cut both round and irregularly shaped holes in making filter sheets for the chemical industry, sieves, and similar products. This type of operation often requires relatively long slender punches crowded close together. For this reason the name perforating is frequently used to describe the piercing of two or more holes in close proximity to each other. Figure 16 shows a typical perforating operation as it might be performed in a progressive die, thus permitting dispersal of the several punches and simplifying die construction. As in all progressive dies, however, the relative location of the holes is subject to ability to feed the stock accurately between the strokes of the press.

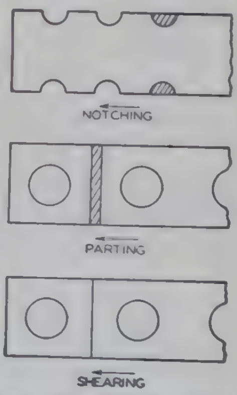

Fig. 17. Typical notching, parting, and slitting operations performed in a progressive die.

NOTCHING is the operation of cutting notches in an edge which may be either curved or straight (Fig. 17). Unlike the four previous operations notching involves cutting along a discontinuous cutting edge. This is accompanied by an unbalance of lateral forces tending to crowd the work away from the punch, thereby making it difficult to control dimensions as accurately as can be done with a continuous cutting edge. Notching is sometimes used as a follow-up operation to blanking, punching, or piercing with the objective of simplifying the contour of the punch and die elements for these operations. Notching is limited only by ability to construct sufficiently rigid tools.

PARTING and **SHEARING** are two similar operations in that their purpose is to separate a part or blank from the stock or from scrap material. Figure 17 shows typical applications of parting and shearing in progressive dies. The main distinction between the two operations is that parting produces some scrap whereas shearing does not. Parting usually involves balanced lateral forces whereas shearing does not. Parting, therefore, can usually be performed with somewhat closer control of dimensions than can be obtained with shearing.

SLITTING is similar to shearing in that cutting progresses along a single discontinuous edge. They differ in that slitting does not extend all the way across a strip of metal and, therefore, does not separate it completely from the adjacent metal. Slitting has many applications, one of which is illustrated in Fig. 18. In this application the slitting is usually followed by a bending operation to create a tab on the component part. Slitting may also be used to free the metal for flow in forming operations in which the metal to be formed is surrounded by large areas of material which would provide too much restraint. A rather minor limitation on the use of slitting is the fact that the metal on adjacent sides of the cut must be displaced relatively, making it necessary to follow up with a flattening operation where this is objectionable.

LANCING is a combined cutting and forming operation with very limited application. It is intended to cut and form the metal so as to produce a louver or similar shape, as shown in Fig. 18. The cut is usually along a straight line, and if the forming is restricted to a displacement approximately equal to the thickness of the stock it creates a projection which can be used to locate one part relative to another where two or more stamped parts are combined to produce component assemblies.
